ACTION AGAINST MATERNITY HOME TRUSTEES AND COMMITTEE OF MANAGEMENT

The hearing of an action before Mr Justice Ayles and a special jury in the King's Bench Division in which one of the three plaintiffs, David Ross, an infant suing by his father, claimed damages for personal injuries received through the alleged negligence of the defendants as trustees of the Crayford Maternity and Nursing Home, the committee of management of the home and Nurse Campbell, a member of the staff, terminated, after proceedings extending over several days, on December 10th, when the members of the jury found them selves unable to agree, and were accordingly discharged without a verdict. The mother of the infant also claimed damages for personal injury and alleged breach of contract and her husband claimed special damages by reason of the injuries to his wife and child. The defendants denied any breach of contract or negligence, or that the plaintiffs suffered any damages as alleged.

It appeared that the infant was born in the home on November 25th 1926. Eight or nine days later, following the usual practice in the establishment he was taken from his mother at 9 p.m. and placed in a cot in a basement kitchen. The cot it was stated was not protected or enclosed and the kitchen floor was about 3 feet below the level of the ground. At about 1.30 a.m. Nurse Campbell who was on night duty heard the infant cry and on going to the cot saw a rat emerge from it and disappear through the window. It was found that the child's face had been hit by Mrs Ross giving evidence said that she was awakened at 6 a.m. and taken down to the kitchen having been told that her baby had met with an accident caused by a rat. She found that the baby's face was bleeding terribly and this gave her so great a shock that her sleep was broken. She and her husband complained that the authorities at the home were negligent in not protecting the cot it being well known that the place was infested by rats. In cross-examination Mrs Ross agreed that but for the accident she had no fault to find with the way in which the home was conducted. She stated that when her doctor visited her he told her she had had a severe shock to her nerves, but she did not tell the matron of the home. After she left the home she was under treatment for two months and had to employ a daily help and a housekeeper.

Dr W. R. Morrison Erith said that his partner attended Mrs Ross in her confinement. He visited the home on the day of the accident and saw the nurse who told him of it and said that they had told Mrs Ross that a rat inflicted the injuries to save her feelings and prevent her being shocked. He saw the baby whose wounds had been dressed with iodine. The right side of the face from the forehead down to the chin had been cut and scratched and bitten in many places. The worst wounds were just below the right eye and a little farther down the cheek. These were bites; the other injuries were scratches. At present the worst deformity was that part of the right eyelid was pulled down by a scar. The scratches were now better but the deformity was bound to be permanent unless something was done. The effect of the accident and the sight of the child on the mother was what it would be on any woman it had upset her nervous system considerably. Mr Ross giving evidence stated that when motor ing with his wife she had twice fauted when rats ran across the road. A gardener formerly employed at the home avowed that during 1923 and 1924 rats were often seen running along the banks of the River Cray by the home and across the lawns and a rat catcher said he had seen rats emerge from out buildings and run across the lawn.

Dr W. A. Rogerson Boxley Heath said that he was honorary medical superintendent of the home at the time of the occurrence. He had attended his own cases there for four or five years and had sent his wife there for convalescence. The home was in every way a fit and proper place for nursing it had a most efficient matron and staff. He had never seen a rat in the home. Answering Mr McVillie for the plaintiffs Dr Rogerson said that he had no recollection of having read a letter sent to the home from the clerk of the local urban council complaining that a report of the occurrence had not been sent to the council. Miss C. E. M. Campbell giving evidence stated that she had been night nurse at the home for the last four years and described the occurrence of the incident after which she stated she at once picked up the baby and ran with him to the matron who was in bed. The infant plaintiff's face was washed and dressed with sterile gauze. It was not true that when Mrs Ross was taken to the kitchen the infant's face was covered with blood.

Dr C. F. Knight Dartford who was medical superintendent of the home till September last said that the babies were put into the kitchen with his approval. He did not think it was a dangerous thing to do. Dr C. M. Ockwell one of the defendants and the medical officer of health for Crayford said that he and his co-trustees had nothing to do with the management of the home. He was medical superintendent for the first two years and it was during that time that the practice was initiated of putting the newborn babies into the kitchen for the night. Evidence was given by a surgeon that he had examined the home in October last and that there were no rat holes in the kitchen and by a sanitary inspector that he had seen no sign of rats in the house and grounds.

On December 10th the matron of the home Miss Maud Walker gave evidence to the effect that she had never seen or heard about any rats in the house before that occurrence. She afterwards

described the events which followed the accident saying that there was no indication while the mother was in the home that she was suffering from shock.

Dr H. W. Barber said that he examined the infant plaintiff on April 11th 1927 when he was brought by his parents to the witness consulting room. There was a scar over the bridge of the nose and one from the inner corner of the right eye also two others beneath the eye and two punctate scars on the forehead. The chief ones were on the area of skin below the right eye. The healing of the scars appeared to be quite sound and there was no pulling down of the lower eyelid.

His Lordship asked Mr McVillie how he made any case against the trustees. Mr McVillie replied that he and his friend had discussed the matter and he did not think his Lordship would be troubled with that point. Counsel addressed the jury and his Lordship summed up. The jury after being absent about two hours intimated that they were unable to agree, and, as already stated were discharged.

Medical News.

The Royal College of Physicians of London will be closed from Saturday, December 22nd, till Saturday, December 29th both days inclusive.

The Christmas lectures at the Royal Institution this year will be on "Sound Waves and their Uses," by Mr Alexander Wood, lecturer in physics in the University of Cambridge. They will be given at the Institution of Electrical Engineers, Victoria Embankment. The general courses of lectures to be given before Lister at the house of the Institution (21, Abchurch Lane), include six lectures on "Evolution and the Problem of Species" by Professor Julian Huxley, and three lectures by Sir William Bragg on "The Early History of X Rays." The Friday evening discourse on March 1st will be by Sir Robert Robertson on the "Infra red Spectra," and on March 22nd by Sir Ernest Rutherford on "Penetrating Radiations."

SESSIONAL meetings of the Royal Sanitary Institute will be held at 90, Buckingham Palace Road, S.W.1, on Tuesday, January 8th, 1929, at 5.30 p.m. and on Friday, February 1st at 5 p.m. Professor Bostock Hill will open a discussion on cleanliness as the basis of health at the first meeting, and at the second there will be a discussion on the civilian population and chemical warfare, introduced by Dr F. R. Humphreys.

The nineteenth annual exhibition of the Physical and Optical Societies will be held from January 8th to 10th, 1929, at the Imperial College of Science, South Kensington. The exhibition will be open in the afternoon from 3 to 6 p.m. and in the evening from 7 to 10 p.m. Lectures will be given at 8 o'clock each evening. On January 8th Professor F. J. Hopwood will describe experiments with high frequency sound waves, on January 9th Mr Conrad Beak will deal with lenses, and on January 10th Mr A. J. Bull will speak on some colour problems in photo-engraving. Tickets, which are required for the first two days, may be obtained from the secretary of the Physical and Optical Societies, 1, Lowther Gardens, S.W.7.

At the annual meeting of the Metropolitan Hospital Sunday Fund at the Mauston House, London, on December 17th it was reported that the amount collected last year was £85,414 showing a decrease on the previous year of £1,520. Collections in the churches amounted to £35,089, this being the smallest total since 1914. The distribution committee reported that 227 institutions, 4 more than in 1927 had applied to participate in the Fund, and recommended the distribution of £81,310.

The fifty-first annual meeting and dinner of the Old Epsomian Club was held at the Trocadero Restaurant on December 13th, and attracted a "record" attendance. The new president, Dr. H. C. Protty of Kettering, was in the chair, and proposed the toast of "Floreat Epsomia," commenting on the value of the influence of the masters at Epsom College on the character of the boys in the earlier years of the history of the school. In responding, the headmaster, Mr. A. C. Powell, mentioned the great services rendered to the club by the late president, Sir Cecil Armitage. He referred to the excellent progress made by the club in the last few years, and then related the more salient scholastic and athletic successes achieved by the school in the previous months. Mr. A. C. C. Parkinson proposed the health of "The Guests in an entertaining speech, and, in replying to it, Dr. J. W. Carr told various witty stories. Mr. G. E. Waugh, in a highly amusing speech waxed reminiscent over the earlier connexion of Dr. H. C. Protty with the school and proposed the toast of his health. The president suitably responded.

A THREE months' course of lectures and demonstrations on clinical practice and on hospital administration for the diploma in public health will be given at the North Eastern Hospital, St Ann's Road, Tottenham, N 15, by Dr E H Thomson, medical superintendent, on Mondays and Wednesdays, at 4.45 p.m., and alternate Saturdays at 11 a.m., commencing on Monday, January 7th, 1929. The fee for the course, which complies with the requirements of the revised regulations of the General Medical Council, is £4 4s. A course under the old regulations may be taken for £3 3s. The fees should be sent to the Clerk of the Metropolitan Asylums Board, Victoria Embankment, E C 4.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are MUSEUM 9561, 9562, 9563, and 9564 (internal exchange four lines).

The TELEGRAPHIC ADDRESSES are

EDITOR of the *British Medical Journal*, Aitology Westcent, London

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.), Articulate Westcent London
MEDICAL SECRETARY, Mediscera Westcent London

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams *Harillus, Dublin* telephone 62550 Dublin) and of the Scottish Office, 7 Drumelough Gardens, Edinburgh (telegrams *Associate, Edinburgh* telephone 24361 Edinburgh).

QUERIES AND ANSWERS.

INCOME TAX

Replacement of Car

"J. K." has been informed by the Inspector of taxes that the allowance is 'either the cost of the new car less the amount received for the old car or the cost of the old car less the amount received for the old car, whichever is the less.' Is this correct?

* * * Yes. There are in effect, two different limits to the amount of the allowance, the first is that a taxpayer cannot claim to deduct more than the out-of-pocket cost—the former of the above alternatives—and the second limit is that the allowance must not extend to the provision of a better car, it must not include further capital outlay. We may perhaps add that the second alternative would not necessarily apply if the cost of cars generally were rising.

Payment under Superannuation Scheme

"F. J. B." holds an appointment and pays £100 a year under a superannuation scheme. What is the appropriate allowance? Can he claim deductions in respect of subscriptions to medical societies?

* * * The question is dealt with in Section 32 (3) of the Income Tax Act 1918 as amplified by Section 26 of the Finance Act of 1920. The result of a somewhat complicated provision is to give payments made in connexion with such a superannuation scheme an allowance equivalent to that given formerly for payments made to life assurance companies under policies to secure deferred annuities. Possibly the regulation which

"F. J. B." has in mind is that relating to compulsory deductions by Act of Parliament. The appropriate allowance therefore is £100 at 2s. 11. "F. J. B.'s" total income does not exceed £1,000, and 3s. in the £ 11 it exceeds £1,000 but not £1,500. The subscriptions can be deducted if membership of the societies in question is a condition of the employment.

Allowance for Children during Education

"W. M." has two sons undergoing medical and dental training as hospital students. The Inspector of taxes returns to the usual rebate on the ground that they are receiving vocational as distinct from educational training.

* * * We assume that the students in question have not yet qualified—special post qualification training might raise difficult questions. On that assumption we are at a loss to understand

the Inspector's attitude in this case, as it seems at variance with general practice elsewhere. If he adheres to his view we suggest that "W. M." might place the facts before the Board of Inland Revenue sending his communication to their Secretary at Somerset House, W C 2.

LETTERS, NOTES, ETC.

TREATMENT OF UTERINE Sepsis

DR MORRIS KRAFS (Harrogate) in the course of a letter on the treatment of septic uterine conditions (puerperal and non puerperal) writes: By a slight modification of the Remington Hobbs method of preparing the patient and using a bivalve speculum I have been able to treat these cases single handed. The patient lies across the bed on a mackintosh with her buttocks well over the edge and towards the light and keeps her knees on to her chest. The legs are covered from foot to groin with warmed towels or a sheet, and 13 pints of antiseptic solution are poured over the vulva. The inner labial surfaces, etc., are cleansed by widely separating the labia, pouring on antiseptic lotion, and finally placing a sterile pad at the vaginal orifice in such a way that the labia when released will keep it in position. Three bowls (flamed) are required one for swab forceps and swabs soaked in antiseptic (but squeezed fairly dry) another containing the bivalve speculum and Hobbs' introducing "forceps" for antiseptic lotion and the third containing a syringe (with a catheter attached) filled with warmed glycerine. The third bowl stands in a basin containing very hot water to ensure that the syringe and glycerine shall remain warm. The operator after preparing his hands knocks down the vulval swab, introduces the speculum, and cleanses the cervix. He now lifts the syringe from the bowl, expresses air from the syringe and catheter and by means of "introducing" forceps raises the free end of the catheter and passes it to the external os. The glycerine is expelled slowly to facilitate the passage of the catheter within the canal and to cleanse the canal from below upwards, a little to-and-fro play on the catheter allows for the return flow. While the patient is being irrigated she is asked to breathe deeply and regularly with her mouth wide open. If she is in severe pain before the treatment her knees should not be drawn up to the chest, but her feet placed on two chairs widely separated. The operator then kneels between the chairs and needs a head light. I use monsol for sterilizing the vulva, etc., and for my own hands, swabs and instruments.

INITIALS IN THE "MEDICAL REGISTER"

THE General Medical Council recently had an application from a medical man whose second Christian name is "Hannah" to have this name substituted in the *Medical Register* by the initial "H." Presumably he found a female name occasionally gave rise to confusion although there have been many instances in history of distinguished men who generally were godsons of queens or great ladies, bearing female Christian names. But it has never been the custom to allow initials to take the place of names in the *Medical Register*. There were a few such cases many years ago and there is still on the *Register* one practitioner whose second name—not initial—is "C." This gentleman, on being written to by the Registrar replied that "C." was his second name so written on his birth certificate and on his diplomas and in these circumstances the Council had no option but to enter it as such on the *Register*. The applicant who wanted to diminish the name "Hannah" to its first letter however, was informed that the Council could not allow the initial to appear but that on complying with the prescribed requirements the second name could be deleted.

AN APPOINTMENT BOOK

WE have received from Messrs John Bale Sons and Danielsson Ltd 83, Great Titchfield Street, W 1 a copy of their *Dental Surgeon's Daily Diary and Appointment Book* for 1929 which enables appointments to be booked for each half hour during the day. Every page opening shows one week. The diary also contains pages for cash entries and an almanack, etc. The price is 7s 6d, or interleaved, 9s 6d.

MIRROR WRITING

MISS M. L. SPACKMAN (Clitheroe Lancashire) writes: Your readers may be interested to hear apropos the article published on December 1st that mirror or looking glass writing is practised more commonly than is usually supposed. Occasionally the more harm accrues of schoolgirls learn it deliberately as a "secret society" method of communicating with each other, and I know a woman of 40 who learned it in this manner and still uses it on postcards even to friends who can read it only through a mirror.

CHRISTMAS MOTORING

THE Automobile Association road patrols will not be on duty in England, Wales, and Ireland on Christmas Day. During the rest of the holiday season the A.A. patrols road service outfits, and night service outfits will continue as usual.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 37, 38, 39, and 42 of our advertisement columns and advertisements as to partnerships, assistantships and locum tenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 276.

An Address

ON

THE DIAGNOSIS OF CANCER OF THE STOMACH.*

BY

WILLIAM GORDON, M.D., F.R.C.P.,

CONSULTING PHYSICIAN TO THE ROYAL DEVON AND EXETER HOSPITAL,
AND TO THE WEST OF ENGLAND EYE INFIRMARY

WITH the knowledge at our disposal cancer of the stomach should often be diagnosed earlier than it is. In the following epitome of the subject I have tried to give just the indications which are certainly useful and to avoid unnecessary repetition.

Practically all clinically discoverable gastric cancers are primary, and almost all are carcinomatous. Gastric sarcoma is a rare disease, probably not accounting for more than 5 per cent of the cases, and, although possible at any age, is only to be seriously considered in patients under 30. It may grow to a very large size, which should be suggestive of its nature. Clinically discoverable secondary cancer I have never met with.

FACTORS IN THE DIAGNOSIS

Let us consider first the chief factors in the diagnosis of primary gastric cancer.

Frequency, Age, and Sex

Cancer of the stomach is now the commonest of all cancers in this country, therefore we must always be on the look out for it. The slight difference in its incidence in males and females is quite unimportant. It is commonly said to be most frequent between the ages of 40 and 60, and that is a very misleading statement, for that is only true of the population at large, and is quite untrue of the patient. The liability to gastric cancer (according to the figures of the Registrar-General) rapidly increases, both for men and women, up to 75, after which it slightly decreases for men and slightly increases for women.

Duration of Symptoms

The disease varies widely in duration, more widely than do most cancers. Some cases, especially in younger people, end within three months. A few last over two years, a very few indeed perhaps to four years. The average duration from the onset of symptoms may perhaps be put at about a year. Symptoms which have lasted more than eighteen months, unless then associated with wasting and cachexia, are unlikely to be due to cancer. Yet once I have seen a woman, stout and rosy, with symptoms which had not varied for two years, who was found at operation to have an extensive carcinoma of the stomach. It is worth while remembering that pyloric growths are more apt to last long than growths further to the left.

Predisposing Conditions

Gastric ulcer sometimes becomes the seat of gastric cancer. A curious difference of opinion has arisen in late years with regard to the frequency of this sequence. The older observers were unanimous that it was unusual. Suddenly someone launched the idea that it was quite common—that as many as 70 per cent of gastric cancers were preceded by a clear clinical history of gastric ulcer. Now, however, an abundance of evidence—clinical, pathological, and radiological—has been accumulated, proving conclusively that the older view was right. The explanation of the mistake would appear to have been faulty pathology. It is, in fact, an important clinical truth that most patients with gastric cancer have not previously suffered from any sort of serious gastric disorder, so that when an elderly person begins to suffer, for the first time in his or her life, from "indigestion," the possibility of cancer of the stomach should at once occur to one's mind.

Heredity counts. When a single case of cancer has occurred in a patient's family too much stress should not be laid upon it, but when several cases have occurred in near relatives we ought to be suspicious.

Locality also counts. When a patient comes from a locality in which cancer is rife—there are such localities—we should be additionally cautious in deciding against cancer.

Significant Symptoms

In rare cases gastric cancer is "latent" in one or other of three ways. Either (1) all characteristics are absent, most often in old and feeble persons, or (2) gastric symptoms are replaced by symptoms either of cachexia or of some complication or intercurrent disease, or (3) gastric symptoms are masked by those of secondary deposits in other organs.

The onset may be either insidious or almost sudden—actually sudden when it takes the form of a hæmorrhage.

The significant symptoms are "indigestion," anorexia, weakness, wasting, anaemia, pain, vomiting, hæmorrhage, tumour, tenderness, fever, offensiveness of breath or vomit, diarrhoea, dysphagia, enlarged supraclavicular glands, oedema of the feet, thrombosis of veins. The "cardiac sign" should always be looked for, and, where there is the slightest chance of radical removal, the x rays, test meals, and search in the stools for "occult blood" should be matters of routine. I will take these in order.

"Indigestion."—Discomfort after meals, fullness, weight, nausea, flatulence, pyrosis, none of them in themselves characteristic, become suspicious when arising for the first time in a person over 40, and still more so when the age is greater. The tongue may be clean or furred.

Anorexia.—Anorexia is one of the earliest symptoms in about 30 per cent of the cases, and sets in sooner or later in 80 per cent. Sometimes ment is especially disliked. Once anorexia begins it generally goes on to be absolute. When present it is highly suggestive of cancer. In a recent paper Dr Villandre says "Carcinoma has been found in practically every case in which there has been aversion from food." Nevertheless there are cases in which the appetite remains excellent.

Weakness.—Weakness which cannot be accounted for is often an early sign, and, when clearly in excess of what the apparent "indigestion" and other conditions present account for, is suggestive. Some loss of weight and anaemia will generally be found as well, if looked for. In cases of "senile heart" it is not sufficiently well known that an unaccountable rapid breakdown of compensation, previously good, may be caused by the superimposition of carcinoma in some abdominal organ.

Wasting.—It is important to remember not only that wasting may be very slight at first, but that treatment may cause a considerable gain in weight, and for a considerable time. A change of diet, combined with washing out of the stomach, has been known to produce a gain of 19 lb, a cheering error of diagnosis has been followed by a gain lasting for three months, and (a curious circumstance still unexplained) an exploratory operation, in which the cancer has been found, has apparently been the cause of an increase of 63½ lb during four months. Sooner or later, however, wasting makes its appearance, and, though it may have been checked for a time, returns and progresses, and thus return is in itself suggestive. Wasting is most marked when an orifice of the stomach is involved. Often the abdomen is first affected, then the breasts, neck, and face. The skin tends in time to become loose and inelastic. Inquiry should, of course, be made as to whether the loss of weight can be fully accounted for by the taking of too little food, since that would deprive it of its special significance. Also the urine will, of course, have been examined for sugar and albumin, tubercle and all causes of fever will have been excluded, and Graves's disease (which may cause surprisingly rapid loss of flesh) proved absent.

A rapid rise in weight in cancer of the stomach may be due to the onset of (1) ascites, (2) pleural effusion, or (3) a rapid and extensive secondary cancer of the liver.

Anaemia.—Anaemia may be of any degree up to producing an appearance which may closely resemble that of pernicious anaemia. But the characters of the blood are

* Delivered to the Exeter Division of the British Medical Association on November 14th, 1922.

those of secondary anaemia, and the failure of treatment, now so successful in pernicious anaemia, would distinguish. Possibly the diseases may occasionally coexist.

Pain—The most important points to remember about pain in gastric cancer are (1) that about 13 per cent of the cases are painless throughout, (2) that pain is present at the onset only in about 33 per cent of the cases, (3) that although at first usually occurring only after food, it tends later to become continuous, and to be not greatly worse after food nor much relieved by vomiting, (4) that recumbency may increase it, (5) that food sometimes relieves it, (6) that it becomes severe at some time or other in nearly half the cases, and that (7) lastly, according to Fenwick, it is apt to be accompanied by a remarkable irritability and restlessness, which he considers suggestive. The characters of the pain are usually not very helpful, but in a recent case I observed the occurrence of the sort of pain which the late Mr. Maimaduko Shield believed to be characteristic of cancer in breast tumours—namely a "sharp, sudden twinge or shoot like an electric shock or the prick of a needle."

Vomiting—Vomiting, like pain, is absent throughout in about 13 per cent of the cases, but it is very rare for both pain and vomiting to be absent together. Vomiting is less often an early symptom than pain, although it is sometimes present at the onset. Frequent vomiting is usual in the later stages, it is often a special feature of diffuse cancerous infiltration of the stomach—so-called "leather-bottle" stomach—which contracts its own cavity as it grows. Vomiting at considerable intervals—such as once in two or three days—of large quantities of dark brown, sour-smelling, frothy liquid is, on the other hand, indicative of gastric dilatation, which may be due to cancer, in this lost condition food eaten days, or even weeks, previously may be found little altered in the vomit.

Haemorrhage—Bleeding may show itself by haematemesis, melaena, or by "occult blood" in the faeces. Haematemesis only occurs in about 33 per cent of the cases, melaena still less commonly, although some amount of bleeding into the stomach probably takes place in every cancer. "Occult blood," therefore, should always be looked for where the diagnosis is in doubt and successful operation is possible. When found, it means at least some form of organic lesion of the stomach. When constant it is strongly suggestive of cancer. When haematemesis occurs it is generally slight and looks like coffee-grounds. In only about 10 per cent of gastric cancers is there a considerable bright red bleeding, such as is so common in gastric ulcer. But such a sudden gush may, in rare cases, be an early symptom. In about 1 per cent haematemesis may be immediately fatal. At a late stage of the disease, when the patient has become very feeble, a serious haemorrhage may only produce syncope and collapse, without vomiting.

Tumour—A tumour is discoverable sooner or later in about 75 per cent of the cases, and it is possible that this proportion might be even greater if examination of the abdomen under an anaesthetic were more often carried out. It is courting failure to delay operation until a tumour is evident, though it is important to remember that a discoverable tumour does not necessarily mean that a successful operation has become impossible. In connexion with the subject of tumour it is desirable to recall the proportions in which different parts of the stomach are affected by cancer. They are as follows:

Pylorus	about	60 per cent
Cardiac orifice	10	
Lesser curvature	10	
Whole stomach	6	
Posterior surface	5	
Greater curvature	3	
Anterior surface	2	
Fundus	1½	

Multiple growths occur in about 3 per cent. Of the various growths pyloric cancers are palpable in about 70 per cent of the cases, growths near the cardiac orifice only in about 50 per cent, since they lie under the ribs and liver, those on the anterior surface and the curvatures in about 80 per cent, whilst those on the posterior surface are usually not palpable at all. We must remember also that a large soft growth may be absolutely under the hand palpating the abdomen and yet be impossible to feel. I

have seen such a growth at operation, its presence had had to be diagnosed without feeling it.

It is also desirable to recall the frequency with which various regions of the abdomen are seats of tumours, thus:

Epigastric and umbilical regions, each about	33 per cent
Hypochondriac regions, right or left each about	16 per cent
Hypogastric region (always pyloric tumours) about	2 per cent

A tumour may rarely be the first sign of trouble. Alas, a tumour may be palpable and diagnostic whilst the patient is still in good general condition. It is necessary to repeat, because so often forgotten, that a tumour which cannot otherwise be felt may often be felt easily under chloroform.

The size, shape, and consistence of the tumour vary greatly. At the pylorus the tumour is generally small, oval, or tubular, firm and sometimes nodular, but matting or infiltration of surrounding structures may alter its character. Elsewhere the masses felt may be soft or firm, regular or irregular in shape. The tumour is often visible as well as palpable. It moves with respiration and can be moved with the hand, often remarkably freely, especially a pyloric tumour, which may be sometimes moved several inches in every direction, unless fixed by adhesions, although it is unwise to assume the absence of adhesions because the movability is fairly free. Pyloric tumours are those which are most often found near the umbilicus—a little above and to the right of the umbilicus is a common position for them. Gas may be sometimes felt to bubble through a pyloric tumour. Cancer of the whole stomach is apt to form an oval or elongated tumour projecting into the epigastrium from under the left ribs with a well-defined lower and an indistinct upper border; this tumour tends to diminish in size as the cancer gets older.

Some tumours only descend from beneath the ribs, *when a deep breath is taken*, so that it should be an invariable rule to ask for such a breath to be taken. Gastric tumours are generally dull on light percussion and resonant on more forcible percussion. A gastric tumour may decrease in size, or even disappear, when extensive sloughing has occurred or when a fistula has formed.

Fever—Fever, like haematemesis, occurs in about 33 per cent of the cases at some time or other. This is often forgotten, and mistakes are made in consequence. I have drawn attention to this source of error, in cancer generally, in a former paper.² In about half the febrile cases the fever is continuous. Chills, headache, and pains in the limbs may be observed, and the temperature sometimes reaches 102° F. or 103° F., though usually only 100° F. or 101° F. Perigastric suppuration is present in some of these febrile cases, and should always be looked for. Considerable leucocytosis of polymorphonuclears would suggest pus.

Offensiveness of Breath and Vomit—These are specially present when gastro-colic fistula has occurred, when the odour may be actually faecal. But offensiveness may occur in absence of fistula, and is suggestive of cancer.

Diarrhoea—This may occur from time to time, and is doubtless due to gastric fermentation. It may be early.

Dysphagia—Dysphagia may occur when the growth is at the cardiac orifice. Then the x-rays should help.

Enlarged Suprarenal Glands—These are quite rarely found. But I remember a case, seen many years ago, where such glands were conspicuous, and formed a chain in the neck, diminishing from below up, they supplied a valuable aid in the diagnosis, the cancer was the most rapidly growing and widely disseminated gastric cancer that I have seen. I refer to it because in Vienna I have found a tendency to deny altogether the value of this "Virchow's gland." Care must, of course, be taken to exclude other causes for the presence of these glands. Their absence has no significance. Obviously this is a late symptom.

Oedema of the Feet—This, in absence of any other cause, should add to the suspicion of malignancy. It is a late symptom.

Thrombosis of Veins—It has been asserted by some German writers that, when the diagnosis of cancer is in doubt, the appearance of thrombosis of veins anywhere makes cancer probable.

"Occult Blood" in the Stool.—The finding of "occult blood" in the stool, if constant, is most suggestive of cancer. Three days of abstinence from all food containing either haemoglobin or chlorophyll must precede the examinations.

Test Meals

The examination of the fasting gastric juice is often essential. The points to be laid stress on are (1) absence or marked diminution of free hydrochloric acid (absent, however, also in some cases of gastritis, in gastric atony, in pernicious anaemia, and in acro-osteitis), (2) presence of lactic acid, (3) foul odour, (4) blood, (5) pus, (6) fragments of growth, and (7) sarcoma in pyloric obstruction. The absence of free hydrochloric acid is very suggestive of cancer, the presence of lactic acid has recently been claimed to be pathognomonic of cancer by Professor Civen Moore and Dr. Roberts, dealing with 22 cases.² It will be most important to confirm this conclusion by a larger number of cases and to determine how early the acid can be discovered. Fragments of growth are conclusive, but are very rarely found.

X Rays

These are of the utmost value in many cases, and when available should invariably be used. But there is no doubt that they sometimes mislead, much, however, depends on the skill of the radiographer. The fact is that here, as in so many other instances, the findings of every method must be correlated with those of every other. In the case of the plump rosy woman here alluded to in the X rays, in the hands of my colleague Dr. Miller Muir, declared unreservedly for cancer. Details of X ray work are outside my province. Dr. Spriggs's valuable recent paper should be carefully read.³ Dr. Mayers's "slow cinematograph camera" seems a most useful advance.

The "Cardiac Sign"

I described this sign in 1903, and twenty five years' experience has only confirmed my original estimate of its great value. It is almost pathognomonic of carcinoma. The only other conditions capable of producing it besides carcinoma are (1) starvation, and (2) severe diarrhoea. These two conditions must, therefore, be always borne in mind when looking for it. It is curious that this sign is usually absent in sarcoma, just as wasting is often absent in the early stages of sarcoma.

The sign consists of a remarkable diminution, which may go on to complete disappearance, of the deep cardiac dullness in the recumbent posture, when there is nothing else to account for it. When the question of carcinoma of some internal organ has arisen, if the recumbent cardiac dullness is found to measure only 1½ inches or less across, instead of the normal 3 to 3½ inches—it is often reduced to the size of a postage-stamp—in the absence of true emphysema as shown by good chest expansion, or of any other chest disease, which could either draw the heart backward or cover it with lung, the odds in favour of the existence of cancer are about 4 to 1, whereas if the recumbent cardiac dullness is of normal width (in the absence of cardiac enlargement or of any chest condition which could either hold the heart forward or retract the lung) the odds are about 4 to 1 against cancer being present. This sign is commonly accompanied by a remarkably feeble pulse and feeble heart sounds.

This "cardiac sign" is apt to be conspicuous in gastric carcinoma cases, and it is rather absurd of people, who cannot make it out, to speak disparagingly of the resources of medical diagnosis. It may be, moreover, an early sign of cancer. I remember a case of cancer (it was of the sigmoid, however) twenty years ago, in which my friend Mr. Russell Coombe and I had made an early diagnosis, and had asked a well known London surgeon (since dead) to operate. He said, "But you cannot diagnose cancer on such slight grounds." We replied that the diagnosis was made, and that we should be obliged if he would accept it. He did, the cancer was found and removed, and the patient is still alive. Another case affords a useful contrast to this. A friend, who had convinced himself of the value of the cardiac sign, sent an early case of ulcerine carcinoma to a gynaecologist of note, and, as he expressed it, "had the

floor well wiped with himself", later the gynaecologist apologized, but operation had then become impossible.

I would suggest the following explanation:

1 The heart tends to become small in carcinoma cases (brown atrophy).

2 The lungs tend to develop a spurious emphysema (Crawford), which I find can be distinguished from true emphysema by the normal expansibility of the chest—a condition perhaps due to a loss of elasticity in the lungs, analogous to the loss of elasticity in the abdominal skin often seen in cases of abdominal carcinoma.

3 The heart muscle doubtless becomes flabby like the skeletal muscles in cancer cases.

4 The small feeble pulse suggests an imperfectly filled vascular system.

In recumbency such a heart should tend to drop back under the anterior chest wall and allow such lungs to overlap it.

Sites of Secondary Growths

Certain sites of secondary growths are worth remembering, as influencing diagnosis. 50 per cent occur in the liver, 35 per cent in the peritoneum and omentum, 19 per cent in the pancreas, and about 10 per cent in the lungs and pleura. Consequently we find, sooner or later, *jaundice* in about 15 per cent of the cases, *ascites* in about 25 per cent, and *pleural effusion* in about 10 per cent. The secondary affections which chiefly tend to mask the primary cancer are cancer of the liver and *ascites*. About 25 per cent of cases of liver cancer are secondary to stomach cancer, and gastric cancer is perhaps the commonest cause of peritoneal cancer.

Other secondary growths occasionally useful in diagnosis, are *skin nodules*, like small tubercles freely movable under the skin. These when microscoped give the diagnosis of cancer, but when very small, unless most carefully examined, may be mistaken for mere lymphoid tissue. Growth in bone may be thought to be "rheumatism", here the X rays can clear up the diagnosis, but bone secondaries are not nearly so common in gastric cancer as in prostatic cancer.

Complications

The occurrence of certain complications not already dealt with must be borne in mind, in order to avoid the mistakes which their presence might cause, such as *General peritonitis*, which occurs in about 3 per cent of the cases and has been recorded as the first indication of the cancer. A *gastric perforation* into the general peritoneal cavity is a rare event. *Perigastric abscess* also occurs in about 3 per cent, and may be sub-phrenic, epigastric, hypochondriac, or umbilical. *Gastric fistula* is found in less than 3 per cent of the cases, usually between stomach and transverse colon, extremely rarely between stomach and small bowel or skin. *Nephritis* may coexist or arise in the course of the disease. *Pneumonia* is an occasional cause of death (6 per cent). *Melancholia*, which may be suicidal, occurs rarely. *Cerebral or spinal symptoms* arise in about 1 per cent of the cases. *Tetany*, *purpura*, and *epilepsia* are all extremely rare. *Phthisis* may coexist, though very seldom, a fact worth remembering. Extension of growth may, in rare cases, set up abscesses in liver, spleen, or kidney.

SOME DISEASES WHICH SIMULATE CANCER

Non cancerous causes of loss of flesh have been already referred to. Blood diseases such as pernicious anaemia, the anaemia of ankylostomiasis, and leucocythaemia, can only be confused with malignant disease by a careless investigator. The commonest difficulties seem to arise in connection with chronic gastritis, gastric and duodenal ulcer or their sequels, hepatic cirrhosis, gastralgia. I will take these in order. The points already dealt with I shall repeat as little as possible.

Chronic Gastritis.—It is from chronic gastritis that the diagnosis has most often to be made, and it is often very difficult in the early stages. Under 30, unless there were a gastric tumour, cancer would not be thought of. But over 40 it should always be thought of, when gastric symptoms arise for the first time. I cannot too strongly

uige the value of the "cardiac sign" in these cases, and of the necessity for the search for "occult blood," and for x-ray investigation

Gastric or Duodenal Ulcer or their Sequels—Apart from the uncommon cases in which cancer supervenes in ulcer, there is usually less difficulty here than with chronic gastritis, for cancer is rare at the earlier ages when ulcer is most common. The duration of ulcer is often much longer than that of cancer, and the symptoms tend to disappear and to recur. Pain in ulcer is usually more severe than in cancer, but less continuous, more aggravated by food, more relieved by vomiting. Appetite in ulcer generally remains good, although the patient may refrain from eating for fear of causing pain. Tenderness over the lesion is apt to be greater in ulcer, although it is a mistake to say (as has been said) that there is no tenderness over a cancer. Vomiting in ulcer is commoner and more regularly associated with meals, and haematemesis is more often profuse and occasional, with perhaps a history of similar haemorrhages some years before. The tumour of an old ulcer may increase the difficulty, and it is important to remember that, even at operation, the nature of the mass may only be determinable by microscopy of an excised portion. I remember a case of another inflammation (not irrelevant) of the pancreas where, at operation, an able surgeon thought we had made a mistake in diagnosis so firm was the mass found and so extensive, but the microscope showed only chronic inflammation, and the recovery of the patient confirmed the microscopy. Except in late and long-lasting cases of ulcer the weakness and wasting are not comparable to those of cancer. Special difficulty arises in cases where cancer has supervened on ulcer, because then the test meal shows a normal or excessive proportion of free hydrochloric acid, as in ordinary ulcer. It should be borne in mind that duodenal cancer is very rare. In some of these cases the x rays render valuable service. Sometimes exploratory operation is indicated, even apart from the question of possible malignancy, as in hour-glass stomach, pyloric stenosis, etc.

Hepatic Cirrhosis—It is sometimes difficult to distinguish the haematemesis of hepatic cirrhosis from that of gastric cancer, and where jaundice or ascites or both coexist the difficulty is increased. The history helps, when we can get it. The sallow faces of cirrhosis, with venous varicosities, are different from the anaemia and thinness of cancer. But there is often wasting in cirrhosis, and cirrhosis may exist without a characteristic faces. The spleen is often enlarged and can be felt in cirrhosis, whereas in cancer the spleen, unless it is involved in the growth (which is rare), cannot be felt. Haematemesis in cirrhosis is apt to be profuse and "coffee-ground," and to occur when there is no loss of flesh. The appearance of toxæmia, such as occurs in hepatic cirrhosis, may decide in favour of cirrhosis. "Hepatic deficiency tests" do not seem to be of much service at present.

Castralgia—This should only be diagnosed when organic disease has been most carefully excluded. I cannot recall a case in which it has caused difficulty, but it is mentioned by others, so I refer to it.

Some Other Tumours

Cancer of the Colon—History, symptoms, and x-ray examination should make the diagnosis plain. Also the direction of visible peristalsis, when present, should distinguish. I remember a case, seen many years ago, before the advent of the x rays, in which visible peristalsis from left to right led me to diagnose gastric cancer, but where the surgeon, summoned from a distance, operated for a colonic growth and found himself wrong.

Cancer of the Head of the Pancreas—Here we have to guide us a fixed tumour (if it be palpable), rapid wasting, white stools without jaundice, or jaundice with enlargement of the gall bladder, together with the diastase reaction, results of estimation of faecal fat and its character, the copious stools, and the microscopical finding in the motions of still striated muscle fibres. It would be also worth looking for possible sugar in the urine (unusual), and to use Cambridge's test and Iodine's test (adrenalin dropped into the eye).

Tumour of the Omentum—A pyloric cancer may simulate this. As I have pointed out in another paper,² the commonness of pyloric cancer as compared with the rarity of omental cancer will help us. But the x rays should be our best guide to a certain diagnosis. The same means of examination should distinguish pyloric cancer from the rather large list of tumours of other organs, which it may simulate in its surprising variety of location in the abdomen.

Simple Gastric Tumour—When such is clinically discoverable exploratory incision will be necessary and will decide.

Lian-ball in the Stomach—This is a possibility not to be forgotten in a hysterical person, and we should ask for a history of lian-swallowing.

Faeces in the Colon—Faeces in the colon may closely simulate a gastric tumour. If the mass can be unmistakably indented with the finger (very rare) then the presence of faeces cannot be doubted, but it is well to remember in such a case that there may also be a growth in the colon causing the faecal obstruction. Generally we must rely on the use of aperients and enemata, together with the x rays, to arrive at our diagnosis.

Aneurysm—Error is easier to make than one might imagine. Expandable pulsation, if found, is distinctive. The x rays may decide.

Gumma—The main thing is to remember it. I have diagnosed such a tumour and watched it disappear under iodide and mercury.

IN CONCLUSION

Four points must never be forgotten in dealing with a case of possible gastric cancer—namely

1 "It is never justifiable to open the abdomen as the sole means of making a diagnosis" (Walton).⁴

2 It is never justifiable to refrain from advising laparotomy when there is reasonable hope of successful radical removal if the general health permits.

3 The diagnosis must be arrived at by a joint use of clinical, radiological, pathological, and, if necessary, surgical means. And the greatest of these are the clinical, because they are the earliest to suggest.

4 "Dyspepsia" is not a diagnosis.

THE SCOPE OF CAESAREAN SECTION.

AN ANALYSIS OF 295 CASES OF THE CLASSICAL OPERATION.*

BY

FRANCES IVENS, M.S. LOND.,

CLINICAL LECTURER IN OBSTETRICS AND GYNAECOL., UNIVERSITY OF LIVERPOOL.

THE scope of Caesarean section is a subject of considerable importance, it is one which it might be possible to discuss, and about which there is some diversity of opinion.

We know that in a certain percentage of cases natural delivery resulting in the birth of a living child is an impossibility, and numerous expedients have been introduced to deal with such cases, none of them absolutely satisfactory or entirely free from danger. The induction of premature labour, prophylactic version, symphysiotomy and pubiotomy, high forceps delivery, all have or have had a vogue, and have been, in skilled hands, more or less successful. Each method, however, presents certain disadvantages. The induction of premature labour, if en-

* Read before the Leeds University Medical Society on November 6th, 1928.

marked upon sufficiently early for a living child to come through a high degree of contracted pelvis, will probably result in the birth of an infant which is weakly and unlikely to survive. Prophylactic version is by no means universally successful, and symphysiotomy and pubiotomy are often maiming and dangerous to the mother from sepsis and from lack of union. A high forceps operation, except in very skilled hands, is an extremely dangerous operation for the mother and is often fatal to the infant. This leaves us with the alternative of craniotomy or Caesarean section. In craniotomy the sacrifice of the child is obligatory, and this is not only repugnant to most obstetricians, but is also an operation by no means devoid of danger to the mother when she is in a state of shock and collapse. It is often difficult and requires prolonged anaesthesia. Caesarean section is the alternative left to us, and we have to consider under what conditions it is a safe operation, and whether in cases where it has hitherto been regarded as unjustifiable any technique can be introduced which will give better results.

The first authentic Caesarean section was probably performed in 1610 by Trautmann of Wittenberg, but for nearly two hundred years the mortality was over 50 per cent., as no sutures were used in the uterus and the patients died from haemorrhage and sepsis. In 1876 Poirro introduced the modification of amputating the body of the uterus and bringing the cervix into the lower angle of the abdominal wound. This operation was fairly successful, but was necessarily a destructive manoeuvre and necessitated a prolonged convalescence. It remained for Sanger in 1882 to introduce the employment of sutures for the uterine incision which made a conservative operation possible. Sanger's operation—known as the classical one, and of which the technique has been very slightly modified since he introduced it—presented certain disadvantages in cases which had been exposed to infection, which had been long in labour, and where other methods of attempted delivery had been tried. Deaths from septicaemia were only too common.

As an improvement, in 1907 Frank introduced a new method—namely the lower segment operation. A transverse incision was made through the lower abdominal wall and the peritoneum was separated from the bladder and from the lower uterine segment, which was then incised, the child delivered by forceps, the placenta removed and the incision closed—the whole operation being extraperitoneal. Though the operation was enthusiastically received it was found that the peritoneum was often torn, and Krönig proposed a modification—namely, the transperitoneal. He opened the abdomen by a median incision and separated the peritoneum from the lower uterine segment, which was then opened by a median vertical incision. These operations have been done scarcely long enough to show whether they are really satisfactory. The proximity of the wound to the vagina is disadvantageous since infection is more likely to occur. The spread of infection in cellular tissues is difficult to control, and it remains to be seen whether the scar in the lower uterine segment will stand the strain of pregnancy or a possible subsequent labour better than one through the muscular tissue of the upper uterine segment.

Vogt has recorded a series of 76 cases of lower segment operation with only 2 maternal deaths, and Küster 55 suspect cases with no maternal death. It must be borne in mind, however, that this operation is more difficult, and it is not yet clear whether there is more or less risk of rupture of the scar in a subsequent pregnancy.

There is no doubt that the classical operation is an easier one, and if it can be performed safely is the one which commends itself to the majority of operators. The advantages are its simplicity, the easy delivery of the child, and the lessened haemorrhage due to the retraction of the muscular wall of the upper segment.

Indications

In the time of Sanger the only indications were a contracted pelvis of high degree or a tumour which made natural delivery an impossibility. In 1898 Lawson Tait suggested Caesarean section for the treatment of placenta

maxim—an innovation which was regarded almost with horror by the conservative obstetric physicians of his day. Since then the indications for Caesarean section have been gradually widening, until at the present time the borderline in contracted pelvis between vaginal delivery and abdominal section lies about a true conjugate of $3\frac{1}{4}$ inches.

Severe eclampsia, accidental haemorrhage, and other toxæmias, an impacted oblique lie, ventroflexion, a rigid or atretic cervix, a narrow vagina in an elderly primigravida, a breech presentation with extended legs in a primigravida, a large child, a brow presentation, a tight contraction ring, serious cardiac disease, pulmonary tuberculosis, or severe bronchitis in the mother—all these have become indications in varying degrees together with other rarer and more unusual conditions. It became obvious that this extension of the scope of the operation presented grave dangers. The classical operation is an easy one and presents no surgical difficulties, and there is no doubt that it began to be employed occasionally in unsuitable cases. Not only is the operation dangerous unless performed with extreme care under proper conditions—for there is the immediate risk of sepsis in a suspect or potentially infected case—but also there is the ultimate risk of a weak uterine scar which may rupture in a subsequent pregnancy.

In 1911 Routh made an inquiry into the results of Caesarean section for contracted pelvis in patients operated on between the years 1891 and 1910. He found that although the mortality in clean cases was between 2 and 4 per cent., in the potentially infected it rose to between 10 and 35 per cent.—not much better than in 1882, when it was over 50 per cent. In 1921 a further series of 4,000 Caesarean sections was investigated by Muir Kerr and Cardley Holland, from hospital statistics in Great Britain and Ireland. Among 3,374 operations for contracted pelvis the mortality in early cases was found to be about 18 per cent. but late in labour and after induction of labour and attempts at delivery it was between 10 and 26 per cent. It was clear that in the suspect case Caesarean section was unjustifiable unless the technique could be improved.

Certain obstetric surgeons have been able individually to present lists of consecutive clean cases with no death—namely, Bar 95 and Schauta 125. But Bar specifically stated that he had most carefully rejected any potentially infected cases, which were dealt with by craniotomy. In Schauta's list of 76 cases of craniotomy on living children the maternal mortality was 1.3 per cent., in craniotomy a dead child there was a maternal mortality of 6 per cent.

The problem before us, therefore, is so to improve our technique that we can operate on the potentially infected case with a risk as low as, or lower than, with craniotomy. The chief danger to be avoided is the spread of sepsis with death from general peritonitis, septicaemia, pulmonary embolism, or septic pneumonia, and it is necessary to think out measures by which we can increase the resisting power of the patient, hunt the infection and aid elimination of toxic products, while at the same time it is essential to obtain a firm uterine scar.

My own technique for suspect cases is one which I adopted after a large experience of the treatment of infected war wounds, where the infecting agents were similar to those attacking the placental site—namely, the haemolytic streptococcus, the *Bacillus coli*, the *Staphylococcus pyogenes aureus*, and, in rare instances, anaerobic organisms such as the *Bacillus aerogenes capsulatus*. I have found this technique successful, and believe that its adoption may help to improve matters very materially.

I propose to give, therefore, a brief account of 295 cases of Caesarean section which have been under my care in hospital and in private during the last nine years, and which have been operated upon either by me or by my assistant surgeon Miss Ruth Nicholson, to whom I am much indebted for her able co-operation and assistance. During this period no craniotomy has been performed when the foetal heart has been heard, and no selection of the cases has been made. A classical Caesarean section has been done in all cases, clean or suspect, even if the patient had been long in labour with ruptured membranes, or if repeated examinations had been made, induction of premature labour performed, or forceps delivery attempted.

Technique for Suspect Cases

The patient is prepared for operation in the usual manner, but no attempt is made to sterilize the vagina. Open ether is employed as an anaesthetic. As rapidity of operation is imperative the classical operation has been invariably performed. The incision is made slightly to the right of the mid line, and the right rectus muscle drawn outwards, so that it will overlap the peritoneal incision. When the abdomen is opened a large gauze dach is placed in the upper angle to protect the intestines. The obliquity of the uterus is corrected and the abdominal wall is pressed firmly against the uterus by the hands of an extra assistant, who helps to push out the uterus as the child is extracted, so that no contaminated liquor amnii enters the peritoneal cavity when the uterus is opened. Large gauze swabs are placed behind and round the uterus, and the placenta is delivered through the uterine wound, all adherent membrane in the lower uterine segment being removed by a swab wiped out of warm saline. The uterus is stimulated to contract and retract by the injection of 5 units of pituitin and 1/100 gram of ergotin, administered when the uterine incision is made. If given too early the uterus contracts so firmly that accurate coaptation of the cut muscular surfaces is difficult. If there is excessive bleeding the uterus is massaged and compressed manually with swabs wiped out of hot saline. In making the incision care is taken to keep above the lower uterine segment, where the bleeding is difficult to control. The uterine incision is then closed by interrupted sutures, an ample bite of muscle being taken with a large curved needle, but the decidua is avoided, so that there is no obvious channel of communication between the infected uterine surface and the peritoneum. No 3 Van Horn twenty-day chromicized catgut is employed for the interrupted sutures, and No 2 for a continuous suture which brings into apposition the peritoneal and superficial muscular layers on each side of the incision, so that the knots of the interrupted sutures are completely buried and a smooth surface is left. The continuous suture is made firm by taking a back stitch at intervals so that no gaping openings are left. With repeated Caesarean sections this method entails the narrowing of the anterior uterine wall quite considerably. I have never done more than four on the same patient. The lower abdomen and uterus are swabbed over with warm saline and the omentum is drawn over the uterine incision. A large rubber drainage tube is placed in the cave of Retzius and fixed in the lower angle of the incision. The abdominal wound is closed by a peritoneal catgut suture and interrupted silkworm gut to include skin and rectus sheath, 20 ounces of rectal saline are administered with the table in the Trendelenburg position, while 10 or 20 ccm of a reliable antistreptococcal serum are injected subcutaneously. Care is taken by compressing the uterus to expel clots per vaginam. The lower abdomen is very firmly bandaged. Specimens of urine, liquor amnii, and placenta or membranes are secured for immediate bacteriological investigation. The Fowler position is adopted. Ten ounces of rectal saline are given every four hours, and the early evacuation of flatus is secured by a turpentine enema on the following morning, and a daily injection of 5 units of pituitrin, which also promotes uterine contractions. Pain and sleeplessness are combated by morphine and calomel and salts or castor oil are given early and freely, even to the production of diarrhoea and incontinence of faeces in very septic cases.

Where lacerations of the vagina, cervix or perineum exist from ineffectual attempts at delivery exudation is promoted by a dressing of 10 per cent hypertonic salt solution to which is added an equal part of 1 in 80 carbolic acid. Should the case progress favourably, with normal pulse and temperature, absence of vomiting and distension the drainage tube is removed in forty-eight hours, by which time a large amount of exudate will have drained away. As soon as bacteriological reports are received the appropriate serum, if available, is given or reported.

The technique for clean cases is very similar but the drainage tube and serum administration are omitted.

For purposes of analysis I have placed my cases in groups, as shown in the accompanying table.

GROUP	Total	Puerperium		Maternal Mortality	Fœtal Mortality
		Afebrile	Febrile		
I Contracted pelvis	228				
A Before or early in labour	133	113	25	0	3 Syphilis 1 Spina bifida 1. Promatritia 1.
B Late in labour—after 12 hours and including cases of obstructed labour	59	29	30	0	6 Spina bifida 2. Asphyxia 1. Jaundice 1. Pemphigus 1. Septicæmia 1.
C After instrumental introduction of premature labour by bongles balloon or stomach tube	24	16	8	0	0
D After attempts at forceps delivery	7	3	4	1	2
II (a) Eclampsia and other toxæmias*	11	7	3	1	5
(b) Accidental hæmorrhage (concoiled)	4	0	3	1	4
III Placenta prævia	22	16	6	0	2
IV Other conditions causing obstructed labour					
(a) Fibroid tumours	3	3	0	0	1
(b) Ovarian cysts	2	2	0	0	0
(c) Ventral fixation	1	1	0	0	0
(d) Rigid or atresia of the cervix	8	7	1	0	0
(e) Excessive size of foetus	4	2	2	0	0
(f) Malpresentation	4	2	2	0	0
V Grave diseases affecting the mother					
(a) Cardiac	7	5	2	1	2
(b) Pulmonary (chronic bronchitis)	1	1	0	0	0

* These included pre-eclamptic conditions, pernicious vomiting, severe albuminuria and uræmia.

I Contracted Pelvis

There were 228 cases in this group, they were divided into four subgroups as shown in the table. A typical infected case is the following:

A primigravida aged 41, with flat pelvis and diagonal conjugate of 4 inches was admitted with membranes ruptured seventy-two hours and meconium-stained offensive liquor. The cervix admitted three fingers. The greater part of the head was still above the brim. Foetal heart 160. The patient was yellow, pulse 104, temperature 100° F. By Caesarean section a white and limp infant of 6 lb 4 oz was extracted with a pressure sore over the left parietal bone. It responded to measures of resuscitation. The wound was drained 20 ccm of antistreptococcal serum were given in a continuous saline subcutaneously a pack soaked in hypertonic salt and 1 in 80 carbolic was placed in the vagina and ergotin and pituitrin were administered. The patient vomited a brownish material almost continuously. Her pulse was rapid and temperature subnormal. She was freely purged with calomel and salts the stomach was washed out and a high rectal wash out given. In spite of some temporary incontinence of faeces the patient made a good recovery. From wound and vaginal streptococci were grown freely.

In only one case of obstructed labour did a fatal result occur. The patient was in an exhausted condition after two separate attempts at forceps delivery, and death was due to septicaemia on the eighth day from a *Staphylococcus aureus* infection. The organism was recovered from the blood. The patient had refused a pelvic examination at an ante-natal clinic.

II (a) Eclampsia and Other Toxæmias

Caesarean section was only performed in special cases where other measures had failed.

Case of Eclampsia—A 2 gravida aged 27 was admitted with a history of scarlet fever when a child, influenza during pregnancy and of recent headaches, oedema and blurring of vision.

She was twenty-eight weeks pregnant and had had three fits before admission. Blood pressure 160/110. The urine was solid with albumin. In spite of morphine 1/4 grain and high colonic lavage ten further fits took place in rapid succession. Pulse and temperature began to rise and as there was no dilatation Caesarean section was performed. The child was stillborn. The placenta was small and full of infarcts; both kidneys were enlarged and the intestines were collapsed. While in the Trendelenburg position 30 oz of rectal saline were given and the stomach was washed out on the table. After operation ten further fits occurred; temperature 101° F, pulse 130. There was some right-sided clonic spasm. The urine contained casts, red blood cells but no pus and the eyes showed albuminuric retinitis and flame-shaped haemorrhages. The last fit took place on the following morning and the patient gradually improved and was discharged in good condition.

The one maternal death in this group occurred in a patient who had had no ante-natal care and was sent in comatose after ten eclamptic fits. She did not recover consciousness. No post-mortem examination was allowed, but a cerebral haemorrhage was suspected. The child was alive when the operation was started.

Case of Lethargic Vomiting—Mrs. S. had vomited during the whole course of her first pregnancy. She was jaundiced and began to vomit coffee-ground material. Labour was induced and a living child was delivered with difficulty as the pelvis was extremely small. Her urine contained coliform organisms and the child died on the fourth day from meningitis. Post-mortem there was no sign of injury to the head.

This patient again became pregnant in 1925 and was quite well for the first three months. She then began to vomit almost continuously, was very constipated and was admitted to hospital. In spite of the usual treatment the vomiting continued. Her temperature was 99° and pulse rate 110. The vomiting became haemorrhagic; the patient was comatose, the pulse poor and the urine contained acetone and diacetic acid, a trace of albumin and coliform organisms. Her condition was so serious that I performed Caesarean section although the patient was only about twenty-six weeks pregnant. On opening the abdomen the intestine were found to be collapsed and sticky. A foetus of 3 lb. was removed from the uterus which was dark in colour. The uterus contracted up but did not bleed. Saline 20 oz. was given subcutaneously during the operation and a large rectal saline which the patient was in the Trendelenburg position. The pulse improved and vomiting ceased very soon. The patient did well.

II (b) Accidental Haemorrhage (continued)

Caesarean section was only chosen in these cases when liminitive measures had failed and there was no dilatation of the cervix. Pituitin was administered freely to aid uterine contractions and no hysterectomy was done. The following was the only fatal case.

A 7 gravida was quite well until 3 a.m. on March 31st 1927 when she woke up complaining of abdominal pain. Nurse and doctor were called and morphine was administered. She complained of severe pain and nausea but did not vomit. Varicose veins were present on the right leg. On admission at 5 p.m. the same day the patient presented a toxic appearance and was quite unconscious; the pulse rate was 140, the temperature 96° and the breathing stertorous. The uterus was hard, no foetal heart could be heard. The urine was solid with albumin. There was dilatation of the os admitting three fingers.

A subcutaneous saline was given and Caesarean section performed at 6 p.m. The uterus was discoloured a mure-green. Blood-stained fluid was found in the peritoneal cavity and subperitoneal haemorrhages were present. A stillborn male child weighing 6 lb. 10 oz. was delivered. Three pounds of retro-placental clot had separated the placenta. The uterus contracted feebly and death took place almost immediately after the close of the operation. The liver, kidneys and uterine muscle showed thrombi, coagulation necrosis, and haemorrhages. A right iliac gland corresponding to the ulcerated leg was double the normal size and showed an increased number of lymphocytes. Bacteriologically the urine contained a mixed growth of *Staphylococcus albus* and streptococci, the varicose ulcer *Staphylococcus albus*, and the placenta non-haemolytic streptococci and *Staphylococcus albus*.

III Placenta Praevia

Caesarean section for placenta praevia has only been undertaken in cases where the placenta was central or overlapping, and where the soft parts were rigid. In practically every case vaginal examinations had been made before admission, and one or more severe haemorrhages had taken place. The same technique was adopted as in suspect cases of contracted pelvis. Special care was taken to secure good uterine retraction, as there is always a risk of post-partum haemorrhage especially a trickling from the cervix. This was not noticeable in any of my cases. Of the two foetal deaths in this group one was due to prematurity and the other to repeated haemorrhages.

IV Other Conditions Causing Obstructed Labour

(a) *Fibroids*—There were three cases in this subgroup. Pannystereotomy was performed in all cases, but in one, as the conditions were unfavourable, hysterectomy was deferred for three weeks; the puerperium was however afebrile. The tumours were large in all cases and had undergone necrobiotic changes. In one case where the infant was stillborn, the placenta was situated over a tumour and the child was obviously very badly nourished. In two of the cases the patients were elderly primigravidae, in the third no child had been borne for nineteen years.

(b) *Ovarian Cysts*—In both of the cases in this subgroup the tumours were non-malignant, and one completely blocked and filled the pelvis.

(c) *Uterine Fixation*—In only one case was Caesarean section necessary for a uterine fixation. It was associated with a slightly contracted pelvis, and a craniotomy had been done previously on a dead child for obstructed labour. The uterus was very firmly fixed anteriorly; the posterior wall was sacculated, and the uterus moved up very considerably when the hand was divided.

(d) *Rigid Os, Atresia of the Cervix* (8 cases)—Into this group fall two interesting cases. In one there was almost complete atresia, with a pinhole aperture in scar tissue from which liquor amni triedled. There was a history of a previous prolonged difficult labour associated with acute gonorrhoeal sepsis. In the other the atresia was complete. There had been one forceps delivery, and the patient was admitted after sixty hours of unrelenting pains in an extremely exhausted condition. She was cyanosed, and the pulse was weak and irregular. No aperture could be found, and the liquor was plentiful and clear.

In another case there was uterine inertia from great distension by twins. The cervix was not dilated, and faint liquor came away. Two living children, who survived, were delivered by section and the patient did well after a febrile puerperium due to a *B. coli* infection, which was treated by some potent anti-coliform serum from the laboratory of Dr. Weinberg at the Pastern Institute.

In four cases of elderly primigravidae the operation was performed for a rigid os, assisted in one with a breech presentation, in another for uterine inertia from small fibroids, and in two for occipito-posterior positions.

(e) *Excessive Size of Foetus*—In three of the four cases in this subgroup the operation was performed for obstructed labour. One case was of special interest. The mother had been previously admitted to hospital for obstructed labour due to a double-headed monster—a case of dicephalus dibrachius dipus—which presented as a breech. The second child though excessively large (11 lb. 8 oz.), was apparently normal.

(f) *Malpresentation*—There were four cases in this subgroup: two brow presentations, one face mento-posterior, and one impacted shoulder. The case of impacted shoulder presentation occurred in a multigravida who had had several normal and forceps deliveries. It was a case of flat pelvis. She had not attended an ante-natal clinic for a month and was admitted fully dilated, having strong uterine contractions. Foul liquor amni was coming away, and there was a marked Bandl's ring. A child weighing 5 lb. 10 oz. was delivered alive, and though it was in a condition of blue asphyxia, revived, 20 ccm. of anti-streptococcal serum and drainage were employed, and the puerperium was afebrile. The patient admitted later that she had examined herself, felt the band, and thought something was wrong. She made an excellent recovery and the child survived.

V Grave Diseases Affecting the Mother

(a) *Cardiac*—In these seven severe cases of morbus cordis Caesarean section was undertaken as being the easiest method of delivery. All the patients did well but one, whose death from a streptococcal pelvic abscess and broncho-pneumonia took place a month later. Sterilization had been attempted by incision and section of the tubes, and it was probable that infection started from the cut tube. Unfortunately no drainage and no antistreptococcal serum had been given, as the case was regarded as a clean one, although she had had several previous forceps deliveries.

(b) *Pulmonary (Chronic Bronchitis)*—The patient was suffering from very severe bronchitis and dilated heart. She could not move in bed without distress, and was extremely emaciated. She was given open ether as an anaesthetic, and did well.

RESULTS

(a) *Immediate*—The maternal mortality, taking all 285 cases together, is 13 per cent, a mortality exactly the same as in Schauta's series of craniotomy on 76 living children, and slightly lower than the 1921 report (Laidley Holland) operation death rate for clean Caesarean section—namely, 1.6 per cent. The foetal and neo-natal mortality is 8.5 per cent, which includes all cases of toxæmia, accidental hæmorrhage, and placenta prævia. The longest series of consecutive cases without a death is 157—namely, from Case 14 to Case 171, during a period of rather more than four years. It is noteworthy that many of the operations were performed in an extremely out-of-date and ill-equipped maternity hospital, and that no patient who had received a prophylactic dose of antistreptococcal serum died of streptococcal septicæmia. I think the serum helps to tide the patient over the first few days of the puerperium, when her resisting power is at a low ebb and her immunity in a negative phase. To be really useful it must be given at the earliest possible moment, and I usually give it during the operation. The one fatal case in a contracted pelvis after attempted forceps delivery was due to infection with *Staphylococcus pyogenes aureus*, a very dangerous organism extremely difficult to combat.

(b) *Ultimate*—I have made many inquiries with regard to the after-history of these cases, and have investigated the uterine scar in about 66 repeat cases. In none which have been treated after the method I have indicated have I found any weakness. Often the scar is imperceptible. I see no reason to discard catgut, which I have found quite reliable. In one case, where the operation had been performed for uræmic convulsions, the patient died subsequently with a ruptured uterus, but in this case, owing to a mistake, a bougie induction had unfortunately been performed. A certain number of cases have since passed through a normal labour or forceps delivery safely. Intestinal adhesions do not appear to have given rise to much trouble, but I have myself operated on one case of intestinal obstruction following a suspect Caesarean section after attempted forceps delivery. If the drainage tube is removed early there does not appear to be an excessive risk of hernia.

In conclusion, I think that these statistics show that craniotomy on the living child is an indefensible operation as a Caesarean section on the above lines involves no extra risk to the mother and gives the expectation of a living child. For central placenta prævia the results for mother and child are so good that it would be well if cases of antepartum hæmorrhage were sent into institutions where surgical measures could be undertaken satisfactorily at the earliest possible moment.

My best thanks are due to my house-surgeons and ward sisters, who help in the care of these patients has been invaluable, and to Dr. Hilda Cantrell who has investigated the records.

SARCOMA OF THE SMALL INTESTINE

BY

P. J. MOIR, M.C., M.B., Ch.B., F.R.C.S.,

HONORARY ASSISTANT SURGEON THE GENERAL INFIRMARY LEEDS,
HONORARY SURGEON LEEDS PUBLIC DISPENSARY,

AND

G. F. WALKER, M.D., M.R.C.P.,

MEDICAL TUTOR AND REGISTRAR UNIVERSITY OF LEEDS

Sarcoma of the small intestine is, of course, a rarity and a clinical curiosity. The object of this paper is to give a brief outline of the subject and to place three cases on record. The literature is very extensive, it is also very dull, being made up of about 200 cases in all. These mostly appear as one-case records, and the notes have a monotonous similarity without broad generalizations. There is a very large transatlantic literature.

Among the very scanty facts which emerge as to the etiology we note a single recorded case in which trauma appeared to be the actual excitant. In another case the disease was found at the site of a tuberculous lesion. In a third case the immediate antecedent to the disease was typhoid fever. Males are affected twice as frequently as females, and the heaviest incidence of the disease falls in early adult life. There are, however, cases on record in every decade of life up to the ninth. The sarcomatous tumour is found most frequently about midway along the small intestine. Either way from this point its incidence lessens. Histologically round-celled sarcoma, lympho-sarcoma, and spindle-celled sarcoma occur with about equal frequency, but there is an example of almost every sort of sarcoma on record. The tendency to glandular invasion and metastatic dissemination is slight. The prognosis does not seem to vary much with either the site or the histology, but it does vary according to the gross morbid anatomy. The morbid anatomy admits of clear classification, thus:

1. The tumour may be a small polypoid mass projecting into the lumen of the gut.
2. There may be an extensive tubular or cuff-like infiltration of the bowel wall.
3. A growth may dangle as a pedunculated mass from the peritoneal surface of the gut.

The symptomatology likewise varies according to the morbid anatomy, but before proceeding to a description

of this certain symptoms common to all three types must be enumerated. These common symptoms are: (a) Precocious cachexia. (b) Heavy toxic and septic absorption with associated anaemia and fever. The fever would seem to be especially noteworthy in children, and the diagnostic difficulties are increased thereby. (c) Alternating constipation and diarrhoea, with malæna often. Vague abdominal discomfort and colic.

THE THREE CLINICAL TYPES OF THE DISEASE

1. The Sarcoma may Project into the Lumen of the Gut as a Small Polypoid Mass

This type would seem to be the most common, and also the one in which the prognosis is least grave. A minute account of such a case was given by Maxwell Telling in which a child of 3½ years complained of symptoms progressively increasing in severity and incidence over several months. The signs and symptoms closely resembled chronic intussusception, but not entirely. At operation a knuckle of small intestine containing an oval button-like mass encroaching into the lumen of the gut was removed. The little mass was found to be a spindle-celled sarcoma. Eight years later the patient was alive and well.

Almost invariably, however, in this type the illness passes through a phase lasting several months in which the general symptoms of cachexia, colic, and fever persist and progress, with a culmination in acute intestinal obstruction due to the polypoid mass precipitating an intussusception.

2. The Growth may take the Form of a Tubular or Cuff-like Infiltration of the Bowel Wall

Here again the general symptoms persist and progress for weeks or months. An acute stage may be reached in several ways. Most commonly an abdominal tumour is discovered, this is taken to be an appendix abscess, or a twisted ovarian cyst, or a hydronephrosis, or a gastric carcinoma. Less commonly subacute intestinal obstruction, erroneously ascribed to a colon growth, takes place. Least commonly a general peritonitis is caused either by necrotic changes in the cuff-like mass or by actual perforation.

3. The Growth may dangle as a Pedunculated Mass from the Peritoneal Surface of the Gut

This is the rarest type and the most grave. As in Type 2, the general symptoms progress till an acute illness

superficies due either to changes in the tumour itself, or to its increasing bulk, or, most rarely of all, to an untortion of a coil of small intestine caused by the freely dangling mass on its surface

CASE RECORDS

CASE 1

A was admitted in 1913 for acute intestinal obstruction found involving the small intestine about

18 inches below the duodeno-jejunal junction. The mass was adherent to the large bowel but it was freed without much difficulty and the whole mass, with the adjacent glands and about two feet of intestine was resected. A lateral anastomosis was done. The naked eye appearance of the specimen suggested a primary glandular condition with adhesion to and ulceration into the small intestine. A portion of the mass abutting into the lumen showed histological structure of a sarcoma with no extraordinary infiltration of eosinophil cells.

The patient was quite well for eleven years. In 1925 she was again admitted for colic abdominal pain and vomiting of several months duration. At operation an annular cauliflower growth was found high up in the small intestine. This was resected together with the adjacent glands. Histologically it showed a sarcomatous structure identical with the tumour removed in 1913.

In 1928 the patient reported herself quite well.

CASE 2

The patient complained of general abdominal colic, nausea, irregular constipation and diarrhoea and abdominal distension for about six weeks. At operation a mass resembling a sloughing cyst was found attached to the small intestine about one foot from the duodeno-jejunal junction. A wide resection and a lateral

anastomosis was performed. Histologically the mass proved to be a spindle-celled sarcoma. One year after the operation the patient reported himself as quite well.

CASE 3

This patient was admitted on account of acute intestinal obstruction of very sudden onset. No definite antecedent illness could be ascertained apart from two attacks of diarrhoea within the last few months. When first seen his condition was very poor, but it was decided to give him the chance of laparotomy. A small intestinal tumour was seen but all that could be done was an ileostomy.

At the post mortem examination the small intestine distension was found to be relieved, but an early acute general peritonitis was the cause of death. About eight feet from the ileo-caecal valve a rhomboidal fleshy mass was found adherent to the small intestine. It dangled from a small base and a pedicle containing some large veins. In bulk it measured about 2 in. by 1 in. by 1 in. Fig. 1 shows the mounted specimen. It had caused acute intestinal obstruction by bringing about torsion of the coil to which it was attached as shown in the photograph (Fig. 2). Histologically the structure was leiomyosarcoma.

We acknowledge with thanks the assistance received from Professor M. J.

Stewart in the pathological and histological details, and to Professor J. T. Dolson and Mr. Richardson for permission to publish Cases 1 and 2.

EPITHELIOMA, ERYTHEMA INDURATUM (?) AND ULTRA-VIOLET RADIATION

BY

J. GOODWIN TOMKINSON, M.D.,

VISITING PHYSICIAN TO THE SKIN WARD AND SKIN ELECTRICIAN,
WESTERN INFIRMARY, GLASGOW. McCALL ANDERSON MEMORIAL
LECTURER IN DERMATOLOGY, UNIVERSITY OF GLASGOW.

At the discussion on ultra violet radiation in dermatology which took place at the Annual Meeting of the British Medical Association held in Edinburgh in July, 1927, the question was raised as to whether there was a risk of carcinoma after ultra-violet radiation comparable to that following upon excessive x-ray therapy. Some considerable time obviously would have to elapse to prove this, and more than a few isolated cases would be required to be of any positive value, as there must be few if any dermatologists who have not seen epithelioma develop on the cicatrices of lupus vulgaris where no physical agent of any description whatsoever—x rays, for instance—had been employed. Such cases are relatively infrequent, but their occurrence is generally admitted and requires to be kept in mind when endeavouring to arrive at the cause of cicatricial malignant degeneration in any given case.

A somewhat arresting case from the point of view of malignant development occurred comparatively recently in my clinic.

About the beginning of 1926 a male adult patient the subject of extensive facial lupus vulgaris who had been treated by a colleague in England with ultra violet rays came under my care in hospital on the latter's recommendation, for further ultra

violet treatment. The patient was submitted to carbon arc light treatment. In the summer of that year a suspicious lesion developed on the left cheek. I discussed with a surgical colleague the possibility of malignancy and a subsequent biopsy showed the growth to be of epitheliomatous nature. Arrangements were made for its excision but the patient disappeared and nothing more has since been seen of him. More than once I inquired if he had been treated at any time with x rays, but invariably got a negative answer, nor can I recall any evidence whatsoever in the shape of pigmentation, telangiectases or atrophic scarring that would suggest excessive x-ray therapy. I could do no other than conclude his statement was accurate.

Exposure to sun rays is included amongst the possible factors in the causation of epithelioma, and the same may be said of the etiology of xeroderma pigmentosum. It would appear, however, that this factor would require the associated one of abnormal vulnerability of the skin of affected persons; otherwise these diseases would be more frequent in countries where sunshine is a constant feature and I am not aware that such is the case. The sometimes familial character of xeroderma pigmentosum would also support this contention. Again, as previously stated, epithelioma may develop on lupus vulgaris where no physical therapeutic agents have been applied. The question naturally arises, Was this epitheliomatous development due to ultra-violet radiation or was it merely coincidental?—a problem obviously offering some difficulty of solution. It might be said, however, that the causation was at least as likely to be independent of treatment as due to it. The patient was of somewhat obstinate temperament, and the regrettable feature of the case was his disappearance—I understand he went to sea—after it had been arranged to excise the lesion.

A case equally interesting as that just recorded, from the point of view of complication, but of entirely different nature, was the following

A girl, aged 19 years suffering from facial and submental lupus vulgaris came under my care in November, 1925, and was put on ultra violet ray treatment, the carbon arc light being employed. After about four months treatment lesions highly suggestive of erythema induratum serofulosorum, one of which broke down, appeared on the legs. Their distribution however, tended to be at a higher level than is usually the case in this affection. I had never practised ultra violet radiation in erythema induratum and as the latter had developed during that treatment

I discontinued it. It is my practice to submit most patients suffering from erythema induratum to x ray therapy employing at the same time appropriate local medication—usually a resorcin ointment and lotion—and advising, where practicable, rest in bed or on a couch in the semi recumbent position. The patient was treated on these lines. X ray treatment was begun in March 1926 a half Snibouraud pastille dose screened with 0.2 aluminium, the pastille remaining unscreened and equidistant from the part exposed and the source of the rays, was given, this was repeated in a fortnight, and again in a little over three weeks—that is, a total dosage of 14 pastilles through 0.2 aluminium filter distributed over a period of a little more than five weeks. This was associated with an ointment and lotion as previously quoted, and rest enjoined. Healing followed. At the margin of the healed ulcer the sole lesion which had ulcerated, an incomplete circle of yellowish colour persisted.

Pigmentation remaining after healing is a recognized feature in erythema induratum, but the unusual tint led me to submit a specimen to the pathological

department for examination, which elicited the following report. The specimen shows a central area with atrophic epidermis surrounded by a swollen area in which the deeper layers show slight increase of pigment granules. No evidence of tuberculous disease is found. As these lesions had developed during ultra violet radiation—and the patient had not spent long hours on her feet—I naturally hesitated about resuming that treatment. However on May 2nd, 1927 I very cautiously began it again and fortunately with no recrudescence of the affection.

Left leg of patient with erythema induratum (?) lesions, the large one shows developing ulceration

PULMONARY ACTINOMYCOSIS.

BY

T. WARWICK PRESTON, M.D. LOND., M.R.O.P.,
ASSISTANT PHYSICIAN, CROYDON GENERAL HOSPITAL.

JAMES HOMER WRIGHT,¹ in his account of pulmonary actinomycosis, says

Definite features are usually wanting until the disease is far advanced. If the lungs are extensively involved there is cough with fetid sometimes bloody, sputum and signs of bronchitis, pulmonary consolidation and cavity formation usually in the lower lobes. Cachexia, anaemia, fever of variable type, and the habitus phthisicus occur also. Frequent involvement of the pleura and thoracic wall are a prominent feature.

Most of the fairly numerous cases which have been reported in the literature from time to time conform more or less closely to the above classical description, and the majority of them have masqueraded for a considerable period as cases of pulmonary tuberculosis. Most of the authors seem agreed also in regarding the pulmonary variety as having the worst prognosis and being the least amenable to treatment. Thus Illich² collected 58 cases without a single recovery. Maier records 7 recoveries out of 35 cases.

Samuel West³ records 30 cases of actinomycosis of the lungs and pleura with 26 deaths, of the remaining 4 patients 1 was apparently cured, the others were discharged with the condition unrelieved, and were subsequently untraced.

Foulerton⁴ reports 14 pulmonary cases from the records of the Middlesex Hospital. 9 patients died, 2 were transferred to the infirmary in a hopeless condition, 1 was

untraced, and 2 were apparently cured. Of the 2 successful cases it would appear that at first operative treatment was employed without producing any favourable effect, cure seems to have been effected in one case by the administration of large doses of potassium iodide, in the other by means of an autogenous vaccine. Rickman Godlee,⁴ after a description of 13 cases of actinomycosis, states his opinion that although potassium iodide is useful, surgical intervention is of primary importance. Of his 4 pulmonary cases 3 patients died, the fourth recovered as the result of surgical intervention followed by the administration of potassium iodide in 40 grain doses three times daily. Bigland and Sergeant⁵ report the case of a man suffering from pulmonary actinomycosis complicated by empyema. The empyema cavity was washed out with collod iodine, the patient, who recovered, also received intravenous injections of iodine, and potassium iodide in large doses by the mouth.

The two cases under my own care, which are described hereafter, seem of sufficient interest to be put on record, first, on account of the somewhat unusual mode of onset, and secondly, on account of their favourable response to simple medical treatment.

CASE I.

A married woman, aged 47 was admitted to Croydon General Hospital on August 11th, 1927, with a history of one week's cough, with offensive expectoration and pyrexia. She looked ill, and had a hectic flush on the cheeks, the temperature was 101° to 102° F. the pulse 128 and the respirations 24. She had an impaired note at the right apex, harsh breath sounds and very striking post tussive suction. She was coughing up thick yellow pus, which smelt so offensively that I made a diagnosis of abscess of the lung although I must confess that I was decidedly puzzled as to its etiology. An x ray photograph showed a dull opaque area at the right apex which however, was less extensive than I had anticipated from the physical signs and from the large quantities of offensive pus which the woman was expectorating. I decided to watch her for a few days before thinking of any surgical procedure, and in the meantime put her on the halcyon and gave her creosote by the mouth and by inhalation.

A specimen of sputum was sent for examination, and on August 15th Dr. Guest reported. The predominant organism is a Gram positive filament, many of the filaments presenting true branching. I have little doubt that this is a case of actinomycosis. On August 18th a further specimen showed the same organism predominating, on August 19th it was still present but in diminished numbers, and there was a profusion of streptococci. On August 22nd, however the streptothrix filaments, showing true branching predominated.

On receiving the pathological report I put the patient on potassium iodide 10 grains three daily by the mouth and started her on a course of intramuscular injections of lipiodol (Lafay) twice weekly commencing with 1 ccm and increasing up to 10 ccm. Altogether she received 87 ccm of lipiodol in this way during her stay in hospital. The iodide was also increased up to 40 grains thrice daily.

On August 27th I injected 20 ccm of lipiodol intratracheally by the crico-thyroid route—the technique employed being that recommended by Chandler⁶—the patient being semi-inverted and turned on her right side. I performed this operation principally in order to obtain a better defined x ray picture of the abscess, but I also had it in mind that the procedure might be of some therapeutic value. The photograph showed dilated bronchi in the upper part of the right lung field, but the lipiodol had not entered into the opaque area of the apparently closed abscess cavity. While of some value from the point of view of localization, therefore, it is doubtful whether my procedure had the desired effect of bringing the lipiodol into contact with the actual area of disease. The cough gradually subsided, and after September 1st the patient had no expectoration.

The temperature remained high (evening 100° to 101° F.) until September 14th after which it was normal until her discharge from hospital on October 10th. At this time she still had an impaired note to percussion at the right apex and a few coarse rales. Her general condition was excellent, and she had no symptoms at all. For two or three months after discharge she took tincture of iodine (French Codex) 5 minims thrice daily in milk after that she had no treatment until October 1928 when I put her on iodine again for a few weeks. At the present time her condition is excellent, and there is nothing abnormal to be detected in her lungs either by physical examination or by x rays.

No "clubs" were ever demonstrated in the sputum, but the branching filaments were so typical on four separate occasions that I do not think there can be any serious doubt as to the correctness of the diagnosis. Wright¹ says that the demonstration of filaments showing true branching justifies the diagnosis, even though clubs are never seen. The patient had never been in contact with horses or other animals and denied ever having chewed grass or straw. She had some vague dyspeptic symptoms, but there was nothing at all to suggest any abdominal focus of disease, a barium meal of the whole alimentary tract showed nothing abnormal.

I must express my great indebtedness to Dr. Christ, who first demonstrated the organism in the sputum. I must also thank Dr. P. W. Hammond, who took the x-ray photographs.

CASE II

A hawker green grocer, aged 65, stated that he had enjoyed good health up to March 1927, except for occasional bronchitis in the winter. In March, however, he had a severe attack of bronchitis. He returned to his work in May, but his cough persisted, and in August he began to expectorate blood-stained sputum. He had never had severe hæmoptysis, but up to the time when I first saw him (September 23rd 1927) he had brought up a little blood nearly every day. He complained of great weakness and said he had lost weight. His doctor had had his sputum tested for tubercle bacilli on several occasions, but with negative result. While sitting in the consulting room he coughed up about a drachm of dark almost "prune-juice" coloured blood. I thought of neoplasm as a likely diagnosis, but an examination of his chest showed nothing but a slightly impaired note at the left base, and a few scattered rhonchi. A radiogram did not help much; the condition being suggestive of an indefinite diffuse fibrosis.

On October 6th Dr. Southgate reported long granular Gram-positive organisms in the sputum suggesting a streptothrix, some of the filaments showed true branching and many pus cells were present. A second specimen showed a streptothrix predominating, and Dr. Southgate expressed himself as having no doubt as to this being the causative organism.

The patient was admitted to hospital and 20 ccm. of lipiodol (Lafay) was administered intratracheally by the crico-thyroid route, the patient being turned over on his left side. The radiogram showed diffuse bronchiectatic dilatations over the left lower lobe but no actual cavitation was apparent. I am of opinion that the procedure was of some therapeutic value in this case, as the lipiodol was carried widely through the bronchial tubes of the left lung. This patient, being afebrile, and able to get about was only kept in in-patient for a few days; treatment being continued in the out-patient department, this was essentially the same as in the previous case—namely, lipiodol intramuscularly and tincture of iodine 5 minims in milk three daily (French Codex).

In January the patient reported that he was feeling well, had very little cough, had brought up no further blood and was putting on weight. A specimen of sputum contained no streptothrix. At the present time he is at work and in good health.

I am greatly indebted to Dr. Southgate, pathologist to Crofton General Hospital for giving me the diagnosis. I must also thank Dr. Herniman-Johnson for his co-operation in the radiological department, and Dr. Easton of Thornton Heath, who sent me this case in the first instance.

THE TEMPERATURE IN PULMONARY TUBERCULOSIS

BY

COLIN MILNE, M.B., CH.B.T.D.

ALTHOUGH the importance of a rise or fall in the body heat as evidence of disease was recognized by Hippocrates its true significance has, curiously enough, rather fallen into the background, and that in an age in which accurate thermometry has become possible (Wunderlich, 1851). Now we require that if the temperature is to serve as a reliable criterion, it must be determined with exactness, various extraneous influences which may modify the correctness of measuring it have to be eliminated.

In view of the long-lasting discussion as to the best way of taking the temperature I investigated the different methods in several series of patients. By taking the oral and rectal temperatures simultaneously, twice daily for three weeks in one series, I found the tracings on the charts to be almost parallel, the rectal being the higher by about half a degree. The rectal temperature is probably the most accurate, its determination being unaffected by external influences, it is therefore recommended by many, but more time is required for taking it and the procedure is not pleasant either for the patient or for the nurse. I found similarly that the oral and axillary temperatures were almost parallel, with an interval between them of about 0.4 of a degree. The axilla must be thoroughly dried for the reading to be accurate, and great care is necessary in the case of patients with a tendency to perspire, as is common in tuberculosis. Taking the temperature of a stream of urine I found most unreliable in practice, the temperature was at least a degree above that of the oral method.

The oral method of determining the temperature seems to me to be the most suitable, but the patient must remain undisturbed for fifteen minutes before it is taken, and keep his mouth closed, otherwise it is cooled by the surrounding air. The thermometer should be left for at least five minutes in the mouth, since even though it is marked as a half-minute or minute thermometer registration is frequently not complete in this time. If the temperature is about normal it is often three minutes before the mercury begins to move at all, though in the case of a temperature of 100° F., or more, this will be recorded within a minute usually. Each patient should have his own thermometer so that these precautions can be observed and the nurse be enabled to read off the results in rapid succession. When there are only two or three thermometers in a ward with eighteen or twenty patients' temperatures near the normal are hardly ever recorded accurately, although marked rises are sufficiently well indicated to be registered sufficiently correctly. An additional reason for having separate thermometers is to prevent one patient from being infected by another, the thermometers being often hastily and imperfectly sterilized in carbolic lotion. There is also more chance of teaching patients to take their own temperatures, so that on returning home they may use the thermometer when they feel out of sorts and be guided as to the need for rest.

All the temperatures mentioned subsequently in this article were taken by the mouth.

What Constitutes a "Temperature"

After looking through the case-sheets of the first 450 male cases admitted to Crofton Sanatorium (1910-15), where there was a complete after-history and a period of residence in the sanatorium of at least six weeks, I have formed the following conclusions concerning male patients in particular.

Some may have a temperature of 98.4° F. or less in the evening with very little "swing" between the morning and evening figures for long periods, during which the disease in the lungs steadily progresses. The evening temperature may continue steadily 99.4° F. in a patient with tubercle bacilli in the sputum, and yet he may be alive and well ten years later. A temperature above 99° F. persistently, especially if accompanied by a pulse rate of 90 or over, is very unfavourable. This is often noted when the larynx is affected. Many cases with an evening temperature of 98.8° or 99° F. do well. Some regard a sub-normal morning temperature, below 97° F., as of unfavourable import, but the after-histories of patients with temperatures of 96.8° and even 96.6° F. do not bear this out, many are still alive after ten years.

It is probable that each individual has his or her particular type of temperature. If this could be obtained while health was good and kept as a permanent record the diagnosis, treatment, and prognosis of pulmonary tuberculosis would be made easier. Even with our present limited knowledge the behaviour of the temperature is a guide to prognosis. In 450 cases with tubercle bacilli in the sputum, the duration of sanatorium treatment being six weeks or more and a definite after-history being obtainable, the results in cases of fever (over 99° F.) were noted and tabulated (see Table I).

TABLE I.—Fever in Sputum Cases
Prognosis of 452 cases from the type of fever

Type of Case	Total	Died in Two Years	Died in Three to Five Years	Lived Six or More Years
Cases with normal temperature	200	82 = 31.5%	34 = 13.1%	144 = 55.4%
Cases with one relapse	5	12 = 34.3%	4 = 11.4%	19 = 54.3%
Cases with fever on admission later normal	50	6 = 12.0%	7 = 14.0%	17 = 34.0%
Cases with two relapses	25	15 = 60.0%	2 = 8.0%	8 = 32.0%
Cases with continued fever	60	50 = 83.3%	6 = 10.0%	5 = 8.3%
Cases with three or more relapses	20	17 = 85.0%	2 = 10.0%	1 = 5.0%

It will be noted that cases with only one relapse had as good a prognosis as those always normal (34.3 per cent. of patients died in two years, as compared with 31.5 per

cent) Cases in which the temperature was raised for several days after admission were uncommon (52 per cent of these patients died in two years), and still more so for cases with two relapses (in 60 per cent death occurred in two years) Cases in which the temperature is continuously above normal, or in which there are many relapses, but with intervals of normal temperature, are about equally serious (83 per cent of these patients died in two years, as compared with 85 per cent) These figures corroborate the conclusions of H. Brenton Porteous,¹ based, however, on the results of treatment on discharge from the sanatorium Gillespie² has also given figures showing how much worse the prognosis is in febrile cases before admission to a sanatorium or treatment of any kind

Ringer³ says that in phthisis "there is probably a daily unnatural elevation of temperature in all cases whilst a deposition of tubercle is taking place, and where the deposition of tubercle has ceased the temperature is normal", and "where there is no elevation of the temperature we may conclude that the progress of the disease is almost insignificant, although the patient is exposed to the lurking danger that from some slight cause this comparatively harmless condition may be aggravated into a severe and dangerous attack"

This explains why the temperature rises in some cases of phthisis and in others it is normal, even though tubercle bacilli are present in both cases But Ringer must have noticed some exceptions, because later he says "A natural temperature must not lead us to conclude that the disease is not slowly progressing since the amount of tuberculation may be too slight to raise the temperature" It will be noted that in Table I 31.5 per cent of the patients had died within two years, but, even so, the prognosis is reasonably good On the other hand, no patient, however seemingly hopeless, should be given a hopeless prognosis, since 8 per cent live five or more years

In the female the rectal, oral, and axillary temperatures also run practically parallel, but the temperature readings differ from those of the male in three important ways (1) Whereas the difference between the morning and evening temperatures in the male is nearly always 1°F or more, in the female the difference is usually less than 1°F (2) The normal temperature in the male is almost always level, but in the female the menstrual cycle is apt to cause a prolonged rise of temperature (3) Even the normal temperature of a female is often much more irregular than that of a male

1 Table II shows that in 90.1 per cent of males the

TABLE II.—Analysis of 1,816 Consecutive Cases to show the Difference between Morning and Evening Temperatures

	Difference of $^{\circ}\text{F}$ or more	Difference of less than 1°F
Males (1,237 cases)	1114 = 90.1%	123 = 9.9%
Females (579 cases)	251 = 43.3%	328 = 56.7%
Female cases in more detail		
Positive sputum (366 cases)	176 = 48.0%	190 = 52.0%
Negative sputum (213 cases)	75 = 35.3%	138 = 64.7%
Female cases with positive sputum		
Temperature raised	128 = 72.7%	16 = 8.4%
Temperature normal ...	48 = 27.3%	174 = 91.6%
Female cases with negative sputum		
Temperature raised	66 = 30.9%	9 = 8.0%
Temperature normal	34 = 34.0%	104 = 52.0%

Out of 360 patients with a normal temperature 278 or 77.2 per cent had a swing of less than 1°F Out of 219 patients with fever 194 , or 88.6 per cent, had a swing of 1°F or more

difference between the morning and evening temperatures is 1°F or more But in 56.7 per cent of the females the difference is less than 1°F In negative sputum cases this is so in 64.7 per cent, as compared with only 52 per cent in positive sputum cases Where there is fever one would expect a bigger swing, and 88.6 per cent of such cases have a difference of 1°F or more But when the temperature was normal 77.2 per cent varied less than 1°F , the difference is often only 0.2° to 0.4°F This kind of temperature is probably common with healthy women

In the literature on tuberculosis, midwifery, and the diseases of women there is very little mention of any variation of the temperature of normal women taken daily for the whole of a menstrual cycle But Reiml (1884) and Giles (1896)⁴ both found that "the temperature is at its lowest point about the middle of the menstrual period, rising then gradually to its maximum a day or two before the beginning of the menstrual bleeding, after which it drops suddenly" Other authorities maintain that the temperature remains unchanged or is altered only occasionally Johnstone⁵ says "There is some reason to believe that the general metabolism of women follows a definite monthly curve, the apex of which is just before menstruation" This could easily affect the temperature

According to the records at Creighton Sanatorium, in a considerable number of females diagnosed as tuberculous there is a definite premenstrual rise of temperature of considerable duration, the temperature being otherwise normal, after a menstrual period the temperature remains

fairly steady at about 97.4°F in the morning and 98.4°F in the evening, until seven or eight days before the next menstrual period, when it gradually rises to perhaps

98.4°F (morning) and 99.2°F (evening) It continues thus until the first or second day of the menstrual flow, when it falls quickly or gradually to the previous steady level In a well marked case the appearance on the chart is like a "valley" and a "plateau" (Chart 1) There is often 1°F of difference between these levels In others careful observation is needed to note the change, for the "plateau" is only 0.2° or 0.4°F above the "valley"

This long premenstrual rise is present in only 34 per cent

TABLE III.—Classification of 276 Female Cases, who were 15 to 40 Years of Age and had been under Sanatorium Treatment for at least Six Weeks, to show the frequency of the Long Premenstrual Rise of Temperature

	Long Premenstrual Rise	Level or Irregular
Cases with positive sputum		
Temperature normal ...	45	55
Temperature raised ..	6	44
Cases with negative sputum		
Temperature normal ..	62	41
Temperature raised ..	4	19

of positive cases, but in 52 per cent of negative cases (Table III) It is not often found when the temperature

CHART 2.

is always elevated From these two data it may be supposed that a long premenstrual rise is probably frequent among healthy females It was present in one (Chart 2) of

two nurses whom I induced to take their temperatures for a month. It would be interesting to get corroboration of this view. In a considerable number of females the tem-

CHART 3

perature shows no alteration at all. Of course in addition, there are the definite manifestations of tuberculous given in the textbooks. There may be a definite febrile relapse before the menses (Chart 3), or the relapse may take

CHART 4

the form of a menstrual or post-menstrual rise of temperature (Chart 4). One girl with a positive sputum had three rises of temperature at intervals of three weeks but then her menstrual period and her temperature remained normal (Chart 5). Most of the relapses in females occur

about the time of the menstrual flow, and therefore at this time special care should be taken. Between the menses a temperature of 98.8° to 99° F is probably febrile,

CHART 5

where is just before menstruation up to 99.4° F may be considered normal. If a female patient is admitted to the sanatorium with a temperature of about 100° F and a few days later the monthly period commences, the outlook for this patient is not as serious as if this temperature occurred midway between periods.*

3. In very few men is there any marked irregularity in the course of a normal temperature, but in women there are quite frequently fluctuations and irregularities. These women are usually of the nervous sickly type. In febrile cases also there are often great variations in the course of the temperature.

CUTANEOUS ALLERGY FOLLOWING DIPHTHERIA ANATOXIN ADMINISTRATION

BY

ARTHUR COMPTON, M.D., D.Sc.,

DIRECTOR, MUNICIPAL PUBLIC HEALTH LABORATORIES, ALEXANDRIA, EGYPT

Urticarial eruptions are a frequent sequel of injections of therapeutic serums and constitute the most prominent symptom of serum fever. On the other hand they are rarely seen following injections of toxin antitoxin (serum) mixture, even with three injections at fortnightly intervals in diphtheria prophylaxis. For instance, Wahl (1927) with a personal experience extending over four years of several thousand children immunized by injections of toxin antitoxin, has recorded only one such observation.

It is not I think, so well known that urticarial symptoms—evidence of an allergic state—may arise in connection with diphtheria immunization with antitoxin. The following case lends itself to interpretation in this way.

A children's nurse aged 17 received three prophylactic injections of diphtheria antitoxin (Institut Pasteur) subcutaneously on July 4th, July 17th and August 2nd 1928. A thirteen-day interval separated the first and second injections, a sixteen-day interval the second and third. The doses given were 0.4, 0.8 and 0.8 c.c.m. respectively. Apart from the usual local redness at the site of inoculation no reaction accompanied the first two injections. On the evening of the third day after the last injection (that is, three days from the beginning) she felt slightly out of sorts and retired early to bed. The next morning she woke up with a swollen puffy face and while attempting to dress she noticed that suddenly everything went dark (2 vertigo).

She was put back to bed and when seen shortly afterwards the eyelids were found to be markedly oedematous and there was a widespread urticarial eruption present over the body, especially noticeable on the legs, thighs and chest attended by itching. This she stated had been present from the night before on her legs and chest. The temperature was 99° F, the pulse 80. The urine of specific gravity 1024 was acid and slightly cloudy. Albumin and sugar were absent, marked excess of indican and excess of creatinins were present. The bowels were regular.

After two days in bed with mild purgation and low diet, the attack completely passed, the eruption lasted from thirty-six to forty-eight hours, during two months since there has been no return.

The patient's past history included measles, chicken pox, and whooping-cough—all before the age of 7—no history of diphtheria or of any injections. She had a tonsillectomy at 7 and thereafter a healthy childhood. A personal history was elicited of a

dietary idiosyncrasy towards eggs, especially the yolk, which she said always made her feel sick. This idiosyncrasy appears to have been indirectly familial, an aunt on the father's side possessed it. It has however to be viewed in a mild and rather relative light in both for the patient has been known to take eggs without inconvenience when served in dressings, custards and other dishes where she was unaware of their presence. The aunt late in life developed diabetes, and then eggs formed an important part of her diet.

The foregoing clinical picture is indicative of an anaphylactoid state. The question arises, Was it of alimentary origin or due to the antitoxin injections? The excess of indican and the personal intolerance towards eggs suggested that the condition might be alimentary. Inquiry in this direction revealed that at lunch the day before the eruption the patient had partaken of clotted milk (*lait caillé*). An article of diet to which she was unaccustomed, there was no history of eggs. It was concluded however that there was little to incriminate in this, a view which has been confirmed since, for she has frequently partaken of the same and other brands of clotted milk without inconvenience of any sort.

By elimination, therefore, the diagnosis of anatoxin allergy was arrived at, the responsible factor being clearly the albumin content of the anatoxin.

Albumin Content of Anatoxin

Anatoxin being a formalized filtrate, from a bacterial culture in nutrient broth, its albumin content naturally depends upon the nature of the broth, and, according to Ramon (1924) also upon the luxuriance of the bacterial culture.

Tested from the point of view of albumin and albumin derivatives, the diphtheria anatoxin employed gave a well-marked positive Heller's test indicating the presence of albumin. This was confirmed by precipitation with trichloroacetic and hydrofluoroacetic acids. The biuret and xanthoproteic tests were positive. Millon's and Adamkiewicz's tests gave negative or indefinite results. Evaluation of the albumin present, with trichloroacetic acid in a Sear and Cantowhe rachalalbuminometer, revealed a content of approximately 0.01 per cent.

This represents a content of 0.0001 gram albumin per c.c.m. The figure is significant, it is practically identical with the recognized albumin content of toxin antitoxin mixture. Now, from the point of view of anaphylaxis,

quantities so small as 0.000001 gram of a pure albumin, like egg albumin or serum albumin, are known to be sufficient to constitute a sensitizing dose for the guinea-pig (d'Hérelle, 1923).

Comment

This case is illustrative of a type of sensitization which, as concerns immunization by diphtheria anatoxin preparations, has hitherto scarcely been noted—namely, sensitization of patients to the albumin of the preparation—that is, to all intents, to the albumin of the nutrient medium employed for the culture of the diphtheria bacillus giving the toxin. In this way the case is instructive, and gives occasion for certain reflections.

Immunization against diphtheria, whether with toxin-antitoxin mixture or with anatoxin, gives apparently good initial immunity, this is deemed of such importance as to overshadow any ultimate inconveniences. Both methods, however, give rise to remote risks, and both to initial risks. The remote risks of toxin-antitoxin injections are so well known as to need only passing mention. The patient becomes sensitized to the horse serum of the antitoxin, and thereby risks anaphylactic manifestations whenever for any reason later in life therapeutic serums may have to be administered. Many clear-cut instances have been described in the literature, notably by Stewart (1926, 1927), Gatewood and Balldridge (1927), and Lathorp (1927). The initial risks of toxin-antitoxin immunization are practically negligible. Hundreds of thousands of children and adults have undergone this immunization during the past four or five years without any definite reaction. In fact, in this respect no particular note of alarm—so far as the literature goes—has been sounded. The case recorded by Wahl, referred to at the beginning of this paper, is one of the very few exceptions and observations of its kind.

This was the case of a 10 months' baby which, after supporting perfectly two injections at a fortnight's interval on the occasion of the third injection, a fortnight later developed respiratory distress, discomfort and within a few minutes a giant urticaria on the face and neck spreading rapidly over the chest, abdomen and lower extremities. All this occurred about ten minutes after the injection. Administration of 7 minims of adrenalin hydrochloride intramuscularly promptly gave relief.

As concerns anatoxin, the remote risks of the order encountered with toxin-antitoxin are believed to be non-existent, and this for two reasons: (1) because the preparation contains no horse serum antigen, and (2) because sensitization reactions are strikingly specific, and only follow reinjections of the same foreign protein antigen. These reasons of themselves are sufficient to justify the present tendency to adopt anatoxin, instead of toxin-antitoxin mixture, as the instrument of immunization in diphtheria. But the present study suggests a possible remote risk of another order.

We have seen that sensitization may occur to the albumin of the anatoxin, or perhaps it would be more correct to say to the nutrient broth entering into its composition. Persons immunized by anatoxin, therefore, should they later in life become subjects for vaccine therapy (and there is no reason to anticipate the popularity of vaccines waning), will require vaccines rigorously free from the albumins of nutrient broth, otherwise accidents may occur during vaccine treatment. Fortunately allowance is already made for this point of view in most "makes" of vaccine, although perhaps not in all. Confirmation, moreover, of this outlook may be found in some recent work of Nicolas and Katrandjeff (1928). Those authors have established that the proteins of meat, after heat coagulation, redissolving in weak alkali, and neutralization, constitute excellent antigens, giving rise to antisera particularly rich in specific precipitins.

Concerning the initial risks of anatoxin immunization, the case here reported speaks for itself. The symptoms were fortunately mild, and gave no more need for alarm than would have done those of any simple case of serum sickness, which this case closely simulated. Its interest, however, mainly lies in indicating that if allergic accidents during the initial period of immunization are to be avoided, there is need to perfect both the preparation of anatoxin and the technique of its administration. It is well known that the birth of the allergic state ("altered reactivity" of cells) is a function of the sensitizing dose

of offending substance and of the time lapsing between its injection and reinjection. The possibility of allergic accidents should, therefore, largely disappear with the advent of anatoxin preparations of lower protein content—if that can be attained—affording protection by fewer injections (for example, two instead of three, as at present recommended) at shorter time intervals between the injections. Hopeful advances along such lines have already been signalled. Srodowski and Chalapina (1927), working with different diphtheria anatoxins of equal antigenic strength (Ramon), but unequal flocculating power, have found that the immunizing action is proportional to the rapidity of flocculation of the initial toxin. Working with such a preparation, they report immunization (Schick negative results) with a single injection in 88.8 and 93.6 per cent of cases, after three weeks and two and a half months respectively, and with two injections in 93.3 and 96 per cent of cases. These figures are based on a sufficiently large clinical material to be impressive: 27,000 children Schick tested, of which 4,600 were vaccinated by anatoxin, and in 1,861 the immunity produced was controlled by the Schick test.

SUMMARY

A case is reported—the first of its kind known to the writer—of allergic symptoms arising in connexion with the use of anatoxin in diphtheria prophylaxis, with general remarks on the risks attending our present-day methods of diphtheria immunization.

A CASE OF GENERALIZED MENINGOCOCCUS INFECTION

BY

A. W. GARDINER, M.B., CH.B.

LATE SENIOR RESIDENT ASSISTANT MEDICAL OFFICER, BOOTH HALL INFIRMARY FOR CHILDREN, MANCHESTER

THE following type of case of meningococcal pyæmia is of rare occurrence, and in one of its features—a double metastatic nido-choroiditis—would appear to be unique. The clinical facts are as follows:

On September 29th 1927, a female child aged 2½ years was admitted to Booth Hall Infirmary. The glands of the right side of the neck had been swollen for seven days and the mother had been massaging these with olive oil. She appeared to be quite well in general health and had been playing until two hours before admission when she vomited and became very ill.

On examination she was found to be in good general condition, but very pale, her temperature was 102° F. and the right cervical glands were moderately swollen, tender, and firm. Her throat appeared to be quite normal but a routine swab was taken and was found to show Klebs-Loeffler bacilli. By evening the temperature fell and the child became comfortable and slept. On the next day the cervical glands had subsided a little but the temperature began to rise, and at night the child was restless and noisy. No further signs or symptoms were discovered until October 2nd when both conjunctivæ became injected, the corneæ were hazy, and the next day there was pus in both anterior chambers. At the same time the small joints of the hands and feet became swollen and several petechial spots appeared on the hands, the lower part of the body and the legs and feet. By evening the elbows and knees had begun to swell and the temperature was high the patient being extremely ill and restless. On October 4th the eyes had improved slightly but the joints were still swollen and did not begin to subside until October 6th. Iris was present in both eyes. At no time was there any demonstrable splenic enlargement nor were there positive signs of meningeal involvement.

By the second week the patient was generally much better, but there was still inflammation of both eyes, and it was soon evident that she did not distinguish light from dark although mentally she was quite bright and intelligent again. The temperature remained above normal for nearly a month.

On October 3rd a sample of spinal fluid was collected but neither this sample nor subsequent ones showed any excess of cells or protein. On the two subsequent days pus was aspirated from the knee joints and found to contain in large numbers a Gram-negative organism having the microscopical characters of the meningococcus. On culture this organism fermented glucose and maltose but not sucrose; it grew freely on serum media at 37° C. but not at room temperature.

On December 8th she was examined by Dr T M Bride consulting ophthalmologist to the infirmary who reported that the right eye was quiet and the cornea clear, there was no keratitis punctata. The anterior chamber was shallow and the pupil irregular with posterior synechiae. The lens was clear but the vitreous was full of a yellowish white exudate. The condition in the left eye was similar to that of the right. Metastatic mottling was present.

Subsequently the child developed bronchopneumonia and recovered. She is now—one year from the start of her illness—quite well and is gaining weight. She is exceptionally intelligent for 3 years of age but is liable to sudden bursts of temper which quickly pass off. This like her mental state generally is no different from what it was previously. She is unfortunately, completely blind. There is no glandular swelling.

Cases of meningococcal septicaemia without meningitis have occurred not infrequently in adults, but apparently very rarely in children. I have noticed references only to two children. Pybus records the case of a girl, aged 3 years, who was taken ill with general septicaemia and died in thirteen hours. Blood cultures yielded a pure growth of the meningococcus, but there was no meningitis. The second case reported by Flach, is that of a child, in contact of a carrier and also of a clinical case who developed arthritis of the knee, which proved to be meningococcal. The cerebro-spinal fluid and the blood, in this instance, were both negative.

There are other instances in which these lesions complicate frank cerebro-spinal meningitis, and there is also an intermediate case in which meningitis developed secondarily, in point of view of time at least, to other meningococcal lesions. In this case a female patient exhibited multiple joint lesions, meningococci being found in the blood, she developed meningitis two months later, but ultimately recovered. It has been suggested in textbooks that septicaemia patients would develop meningitis if they lived, and while this is strongly supported in the case quoted above, it is equally tenable that they need not. It is twelve months since the acute stage of the case reported here, during this time the child has been under constant hospital observation, without showing any signs of meningitis. Careful questioning of the parents fails to reveal any meningitis prior to admission.

The adenitis is interesting in view of the fact that it is an unusual complication in the early stage of meningitis when the organism is presumably in the throat. In a series of cases of meningitis studied by Worster-Drought and Mills Kennedy only one patient developed adenitis, and this was late in the disease. Fairley and Stewart state that with them a few of the convalescent patients developed adenitis. To account for its occurrence in the present case we must presume that it was due to some other infection of the tonsils on which, later, the meningococcal infection was superimposed. From a consideration of the rash and the temperature chart in this case it would appear that the meningococcal infection occurred just before admission to hospital—that is, when the child suddenly became ill, possibly with a rigor. The rash was purely petechial and several of the spots suppurated. The face in this particular case escaped. The joint lesions were more widespread than is usual, and were of the nature of a synovitis. There was, after the neutenness diminished, a rapid complete recovery in all of them.

Irido-choroiditis occurs only in meningococcal meningitis and is usually unilateral. I have not been able to find any record of bilateral irido-choroiditis occurring in any case similar to this. Throughout the illness there was a varying amount of enteritis. The Klebs-Loeffler infection of the throat did not appear to give any special symptoms and persisted for many weeks. As soon as the nature of the infection was established specific treatment was commenced in the form of anti-meningococcal serum, given intrathecally and intramuscularly.

In view of the recovery, it is interesting to contrast this with the same disease in adults. According to Heringham the disease commences with "malaise not severe enough altogether to prevent duty, lasting from three to seven days" followed by a severe illness which is fatal in four days.

My thanks are due to Dr G D Dawson for permission to use the bacteriological reports, to Dr T M Bride for the report on the final condition of the eyes, and to the medical superintendent, Dr D Ewart for his assistance in connexion with this case.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL

STATUS LYMPHATICUS

I CONSIDER the two following cases of status lymphaticus, which occurred in the same family, so unusual as to merit being recorded.

On the evening of October 6th in response to an urgent summons I visited a young woman, aged 30 years, and on arrival found she had been extinct some fifteen minutes. Though I had attended other members of her family I had never before seen her—in fact was unaware of her existence. Owing to her nervous temperament and liability to epileptic attacks she was shunned by her family from all undue excitement. Her parents description of her epileptic fits of some years duration, and for which she had at one time received hospital treatment, lead me to conclude that they were of the nature of petit mal. She was of medium height, fat, and healthy.

In communicating with the coroner I explained that her epileptic attacks were too trifling to be an adequate cause of death so he ordered a post mortem examination, which revealed the following abnormal features. The persistence of a thymus gland over 1 oz in weight. An enlarged heart—13½ oz in weight—showing no sign of disease but an unusual amount of fatty infiltration. An enlarged spleen—8½ oz in weight—soft and hyperaemic. The brain and other organs were quite healthy and there did not appear to be any hyperplasia of lymphatic structures. Death was obviously due to status lymphaticus and accelerated by unusual excitement—a wedding that day in the family.

Sixteen months previously a sister aged 25 years, a quondam patient suddenly expired in a dancing hall in London. A necropsy at the Middlesex Hospital revealed status lymphaticus as the cause of death.

JAMES CILCHRIST, M A, M D, Ch B,
Surgeon to South Eastern Hospital for Children S.E.25

RAT-BITE FEVER IN HONG-KONG

SINCE this case of rat-bite fever is the first of its kind to be reported in Hong-Kong it may be worthy of publication.

On September 25th a Chinese man aged 32 was bitten by a rat (*Rattus decumanus*) about the middle of the upper border of the left trapezius muscle, the bite was a small puncture. There were no symptoms till October 7th twelve days after the bite when the temperature rose and a raised violet-coloured circle appeared round the bite. On October 17th, ten days after the rise of temperature a rash developed. The patient was seen on the eleventh day of fever when his condition was as follows. The bite was represented by a callous ulcer 1 inch in diameter around it was a purple indurated ring 1½ inches wide. From the ulcer to the middle of the anterior fold of the axilla ran a purple streak 1½ inches broad. Under the anterior axillary fold were a few hard glands. Spread over the face, body, arms, and thighs was a rash which began as a faint pink raised macule about 1/4 inch in diameter in the course of a few hours it assumed a bluish tinge. It was most marked on the face, along each side of the spine where the spots coalesced in places, and over the shoulder blades and was very similar to that of typhus fever. The fever was of the continuous type between 100° to 103° F each day at its height there was usually vomiting and some sweating. Mental symptoms were marked there was some delirium at night and delusions that cockroaches were running over him. Pain was intense in the region of the bite there were also articular and muscular pains so severe that the patient expressed a wish to commit suicide.

A search was made in the blood for the spirochaete both in stained slides and with the dark ground but none was identified. 10 ccm of blood was cultured but no growth of organisms was obtained. There was no leucocytosis and the differential count was polymorphonuclears 69 per cent, large mononuclears 18 per cent, small mononuclears 7 per cent, large lymphocytes 6 per cent, eosinophils nil. He was too ill to postpone treatment and on the twelfth day of fever 0.45 gram of novarsenobenzol was given. Six hours later he was vomiting and the temperature was 103°, twenty-four hours after the injection he sweated profusely the temperature fell to normal and all pain ceased thirty-six hours after the injection the purple areola round the wound had gone and the lymphangitis over the pectoral muscle had nearly faded. The rash was still faintly visible and in many places had become a brown stain. He expressed himself as being perfectly well. This dramatic effect of arsenical injections is apparently diagnostic of the disease.

SPONTANEOUS RESTITUTION OF AN INVERTED UTERUS

At a meeting of the North of England Obstetrical and Gynaecological Society at Sheffield on November 23rd, the president, Mr H. LEITH MURRAY (Liverpool), in the chair, Professor MILES H. PHILLIPS (Sheffield) described a case of spontaneous restitution of an inverted uterus.

Professor Miles Phillips said it was generally conceded that it was highly dangerous to replace the recently inverted uterus while the patient was suffering from shock, but it was perhaps not so well recognized that the infected and inflamed inverted uterus should also be allowed to remain in its undignified position. Apart from the danger of lacerating the softened organ there was the risk of generalizing the septic processes by damaging the barriers to the spread of infection which nature had set up. Those who employed local applications, such as glycine or hypertonic saline solution, to the acutely infected endometrium would also recognize that it was by no means a disadvantage to have the uterus inside out. It was well known that involution would take place fully while the uterus was inside out. Experience had shown that there was another good reason for advocating this expectant attitude. In quite a number of cases spontaneous reinversion had taken place during the treatment. He reviewed the literature on the subject, and gave an account of his own case.

A primipara was sent to the Jessop Hospital on September 29th, the twelfth day of the puerperium, a lump having suddenly appeared at the vulva. Half an hour later her doctor returned it into the vagina and sent her to hospital as a case of inversion.

The patient looked acutely ill and profoundly blanched; she had a pulse rate of 150 and a temperature of 100.6° F. The completely inverted uterus filled the capacious vagina. It was covered by superficial grey sloughs. The scanty vaginal discharge was very offensive. It was arranged to pour a solution of glycine and glutamine into the vagina daily and next day she was transferred to the open air ward for puerperal sepsis at Norton Hall. On this day the temperature reached 103° F. A blood culture was found to be sterile but streptococci and staphylococci were recovered from swabs from the uterine surface. An intravenous infusion of half a litre of citrated blood was given.

On the next day a brisk haemorrhage occurred, it was impossible to see the bleeding point but the blood appeared to be coming from the vaginal vault. The house surgeon packed the vagina and gave 1 c.cm. of haemoplastin. Next day a second haemorrhage was treated in the same way. The vaginal discharge remained very offensive, and the glycine was replaced by hot saline douches. On October 9th a second blood transfusion (600 c.cm.) was given. Her colour improved but the temperature and pulse rate were still high.

On October 18th the house surgeon noted that the inverted uterus was certainly smaller and of a redder colour. A few hours later Professor Phillips examined the vagina with a Sims speculum and found a very great change; the body of the uterus had disappeared, the rim of the cervix was now visible, and within it lay a lobed mass of obviously placental tissue. He thought it wiser to leave this for the time being since the daily temperature still fluctuated between 99° and 101° F. but it was arranged that should another haemorrhage occur the placental fragments were to be removed. Next morning bleeding did occur; the patient was promptly anaesthetized and a lump of placenta was easily peeled off though firmly adherent just above the internal os anteriorly. The uterus could now be felt bimanually and was surprisingly well involutioned.

After this the patient steadily improved and was fit to go home three weeks later. It was not possible to get accurate details of her confinement and early puerperium, but she had had a quick and natural delivery of a large child. The placenta had followed soon after helped the doctor thought by "a slight push" and all seemed to be well. A few hours later however she had had two bad flooding bouts, the second accompanied by a lot of pain, possibly the inversion started then. During the next twelve days, apart from anaemia and a slight pyrexia she was thought to be going on well when while micturating, the inverted uterus suddenly appeared at the vulva.

The cotyledon of placenta which had been retained had not been met at the confinement possibly it was incarcerated. Being attached to an area immediately above the internal os it had lain hidden from view in the vaginal vault so long as the uterus was inverted.

Professor Miles Phillips added that if the routine daily measurement of the involutioned uterus had been made in the first week of the puerperium it was possible that the abnormal state of things would have been discovered sooner.

Sarcoma of the Vulva

Mr A. A. GEMMELL (Liverpool) described a case of sarcoma of the vulva.

The patient, a 2 para, aged 54, had been seen by him on February 15th, 1927, the menopause had occurred seven years previously. She complained of a lump in the vulva which had been present for fourteen months and was gradually growing larger. It had been painful for the last two months especially on walking. In 1924 she had had a tumour removed from the left labium majus. No pathological examination had been made of this but it was believed to be a Bartholinian abscess.

A mass the size of a tangerine orange was found in the lower part of the left labium majus, but lifting up its upper part and extending under the vaginal mucous membrane towards the urethra. This mass was attached deeply but the skin moved over it. There was a much smaller mass anterior to this, extending towards the inguinal canal in which there was a hernia. Posteriorly, in the interior part of the perineum on the left side, there was a third mass the size of a golf ball, which was mobile. There was no superficial ulceration and no involvement of lymphatic glands.

Eight days later the masses were excised. The main mass did not extend so close to the urethra as had been expected but had to be cut away from the pubic bone. The small anterior mass was excised with the main mass. During digital exploration of the posterior mass the finger slipped into a capsule and the growth shelled out with great ease. The patient left the hospital on March 20th 1927, with the wound well healed. She later developed severe headache and proptosis of the left eye and died in the following August.

Mr Gemmell said that sections of the tumours, which were all of the same nature, showed that the growth was obviously a sarcoma, spindle and polyhedral cells were arranged round blood vessels with degenerated areas in between the masses. The type of cells and their arrangement in places round vessels, the areas of necrosis, with other compact areas of tumour cells, corresponded with Ewing's description of a perithelioma and therefore Mr Gemmell considered it to be such. He had not been able to find any accounts of perithelioma of the vulva in literature. Ewing had stated that they might arise from the loose subcutaneous tissue of the perineal region, but in view of the history of a previous mass in the left labium in this case it would appear that the origin was definitely vulval. He could not offer any explanation as to why the posterior mass remained encapsulated.

An Unusual Face or Brow Presentation

Professor DOUGAL (Manchester) read notes of an unusual variety of face or brow presentation.

A primigravida aged 25, sent for the midwife at 2 a.m. on November 9th, when the membranes ruptured this being the first sign that labour had commenced. Pains were strong but as progress was unsatisfactory a doctor was called to see the case at 5.30 a.m. on November 10th. He found the os fully dilated but the presenting part high and indefinite. Twelve hours later the patient had made little progress, but he was now able to make out a face presentation. The face was fairly high in the pelvis and the child's mouth wide open and directed forwards and to the right side. The lower jaw of the child was out of reach and evidently held back by the pubic ramus on that side.

Professor Dougal saw the case about midday on November 11th, when the situation was practically the same except that the presenting part was rather lower in the pelvis. The patient was having violent pains, but her general condition was perfectly good. On holding back the perineum with the fingers it was possible to see the orbital ridges, eyes, upper lip, and open mouth of the child; the caput was well marked over the eyes, nose and upper lip, the last being much swollen and resembling a large polypus.

Careful examination under anaesthesia showed the head to be lying in the right mento-anterior position with the lower jaw firmly caught above, a little to the right of the symphysis.

Professor Dougal inserted his hand into the vagina, pushed up the presenting part and flexed the lower jaw, which came down with a distinct click. The presentation was now a simple face with the chin anterior and he was able to complete delivery with forceps quite easily. The child was alive and weighed 6½ lb. Its appearance was anything but prepossessing as there was a large caput over the face; the lower jaw was so much displaced backwards that the child appeared completely devoid of chin. The mother's pelvis was apparently normal.

Professor Dougal said there was doubt whether the case should be considered a brow or a face presentation. Face presentations were generally secondary and passed through the brow stage. Assuming that the brow presented in the first instance, there was an attempt at further extension into a face presentation, but owing to the chin catching on the pelvic rim and so extending the lower jaw, the full face was unable to descend, and labour was therefore obstructed. He had never met with a similar case before.

nor could he find any reference to the occurrence in any textbook. There was an illustration in Edgar's book showing a child presenting by the brow with the mouth wide open, but the head was not so extended and the jaw itself did not appear to be the cause of obstruction.

Unicornuate Uterus

Professor Dougal then showed a specimen of unicornuate uterus which was thought to be an example of a bicornuate uterus with a rudimentary horn, but the latter was so poorly developed that it could not be definitely recognized as such. Part of the specimen had been removed at operation; the remainder at the necropsy.

The patient had profound anaemia associated with profuse uterine haemorrhage, and hysterectomy was undertaken as a last resort. On opening the abdomen the uterine horn was found placed transversely in the pelvis with the fundus close to the right pelvic wall, and the right ovary and tube lying behind it. To the left of the horn was the convexity of the upper surface of the bladder and running across this towards the internal abdominal ring was a flattened band. The left broad ligament was absent. At the internal abdominal ring the band was joined by the lower pole of the ovary and then passed into the inguinal canal as a thick fibro-muscular structure. The ovary itself was much elongated, measuring $4\frac{1}{2}$ inches in length; it extended vertically upwards into the lumbar region, where it was attached to the posterior abdominal wall by a short mesovarium. Lying in close proximity to the upper pole of the ovary was an isolated tubal ostium surrounded by typical fimbriae. No other part of the left tube was visible. The left kidney and ureter were absent. The cervix and vagina were both single, and the external genitals were normal.

Haematocolpos

Professor Dougal also described a case of haematocolpos.

The patient was aged 12 years and 11 months and was admitted to the Royal Infirmary as an urgent case on account of abdominal pain. Menstrual haemorrhage had not yet appeared, but for the last six months there had been severe abdominal pain occurring at monthly intervals and accompanied by nausea and vomiting. The previous medical history was bad. The mental development was below normal at the age of 2 years; several toes had been amputated for gangrene and there was believed to have been some tuberculous disease of the lungs.

On examination the patient appeared to be quite healthy though below the average as regards mental development. Palpation of the abdomen revealed a small firm swelling in the mid line just below the umbilicus and recognized subsequently as the body of the uterus. Inspection of the external genitals showed them to be normal and fully developed, including the hymen. The vagina formed a cul-de-sac about $1\frac{1}{2}$ inches deep, and no cervix could be felt above there was no discoloration nor bulging and no palpable tumour. On rectal examination a cystic mass about the size of a foetal head was felt high in the pelvis and to the right and behind the rectum. On the top of this swelling was the firm mass previously made out on abdominal examination. The pathological lesion was evidently an atresia of the upper part of the vagina with retention of glandular secretions or menstrual blood and surgical intervention was obviously indicated.

At the operation soon after admission an attempt was made to reach the tumour from below by incising the upper end of the vagina. This was unsuccessful as the mass was too high and the amount of intervening tissue too great. The abdomen was then opened and a somewhat distended uterus was found perched on top of a large cystic tumour, which in turn rested on the pelvic floor. An incision was made into the anterior surface of the tumour just below the level of the uterus and about a pint of typical haematocolpos fluid evacuated. Another opening was made through the lower end of what was evidently the distended upper half of the vagina, but this was still above the level of the pelvic floor and well above the lower cul-de-sac. An assistant then pushed up a pair of forceps from below and by cutting down on the points of this instrument a way through was established and a length of gauze stitched to the lower end of the distended upper vagina brought down and through the vulva. The anterior opening into the upper part of the vagina and the abdominal incision were then closed and the patient once more placed in the lithotomy position when the upper part of the vagina was pulled down by traction on the gauze and stitched to the lower end of the canal. The operation was somewhat difficult and tedious but the patient made a good recovery. On examination under anaesthesia sixteen days later the complete vagina was found to be secure and patent and a finger could be passed up to the cervix.

Professor Dougal said that the case was an example of high haematocolpos with some degree of haematometra. The tubes were open and a certain amount of regurgitation of menstrual blood had evidently occurred into the abdomen, for the peritoneal surfaces of the tubes and peritoneal covering of the utero-vesical pouch were stained with old blood pigment. The interesting features of the case were:

(1) The early age at which the symptoms had developed, the menstrual function evidently commenced about the age of 12. Professor Dougal said he had operated on a number of haematocolpos cases, but usually between the ages of 15

and 18. (2) The high situation of the atresia, there was a bulging into the lower part of the vagina and it was impossible to reach the swelling from below. The speaker suggested that it was a mistake to regard all these cases as of developmental origin. Might they not be due to acquired atresia following inflammatory conditions occurring in the genital canal during early life?

Vaginal Cyst Causing Genital Prolapse

Dr O. P. BRYANT (Manchester) showed a specimen of vaginal cyst which had been associated with genital prolapse in a multipara. He said that the specimen had been removed from a single nulliparous woman approaching the age of 40, who also had a complete uterine procidentia, which at first sight appeared to be a typical example of classical prolapse of third degree. The anterior vaginal wall with the cyst was the first to present at the vulva, and was followed by the cervix; there was no elongation of the cervix and no cystocele, even after removal of the cyst. The specimen consisted of part of the cervix and the anterior vaginal wall, to which was attached the cyst. The incisions were those of the ordinary "Fothergill" colporrhaphy, namely a wide anterior racquet incision for amputation of the cervix. The only type of prolapse he had seen previously in a nullipara was the long cervix type. This case appeared to belong to the classical type, with the cyst playing the part of the usual cystocele. A chronic bronchitis provided in this case the factor of strain.

A Test for Patency of the Fallopian Tubes

Mr A. GORAN (Leeds) read a note describing a simple method of testing the patency of the Fallopian tubes. He said that the usual method of insufflation with gas (Rubin) required special and rather complicated apparatus. In the method he advocated saline solution was injected under its own hydrostatic pressure. Owing to the small calibre of the Fallopian tubes the passage of fluid through them was very slow, but it could be made evident with the help of a simple device. The apparatus could be employed in any operation theatre. It consisted of eight feet of rubber tubing with a funnel at one end and at the other end the conical nozzle of a Higginson syringe. About two feet from the nozzle the tube was interrupted by a "drop-counter." It was important that the various junctions should be perfectly tight, so as to allow no leakage. A jug of sterile normal saline solution at 105° F was required. With the patient in the lithotomy position the cervix was seized with a vulsellum and dilated up to No. 10 or so. An assistant, standing on a stool to attain the necessary height, took charge of the funnel and the jug of saline. The solution was poured in until it flowed out through the lower end. The operator tested the apparatus by blocking the nozzle with his thumb to satisfy himself that there was no leak; the nozzle was then firmly pressed into the cervix so as to make a water-tight junction. When the Fallopian tubes were blocked the fluid did not run, or, if at first a small amount entered, the flow soon ceased. If one or both tubes were patent the fluid was seen to drip steadily through the drop-counter generally at the rate of two or three drops per second. The pressure required might be from four to eight feet, corresponding to 100-200 mm of mercury. With this apparatus it was impossible to employ a dangerous pressure, since the pressure could not exceed eight feet of water.

DISORDERED NEURO-MUSCULAR COORDINATION IN CHILDREN

At a meeting of the Brighton and Sussex Medico-Chirurgical Society on December 6th, with the president, Mr GEOFFREY BITE, in the chair, Professor F. S. LANGMEAD read a paper entitled some disorders of neuro-muscular co-ordination in children.

Professor Langmead dealt with that group of disorders in which there was obstruction to a muscular tube at a certain level, and dilatation and hypertrophy of the tube above it, but for which no structural cause could be found. Within this group of "idiopathic" dilatations and hypertrophies he included arthropspasm (achnasia),

Hirschsprung's disease, certain cases of anal spasm, congenital hypertrophy, and dilatation of the bladder or ureters, and idiopathic hydronephrosis. He ascribed the various disorders to unco-ordinate action of nerve impulses, and gave reasons for supposing that they were analogous. It was interesting to speculate how often the nervous dysfunctioning was congenital, as a contribution to this aspect of the subject the speaker gave examples of cases starting at birth or in early life of each member of the group. Describing cardiospasm (achalasia of the cardia) he recounted two cases beginning at or near birth, in one of which complete symptomatic cure had followed treatment by suggestion and persuasion only, he referred to several other cases commencing in early life. Tetany had been recorded as occurring in idiopathic oesophagectasis and also in Hirschsprung's disease. As an example of the latter association he reported a case which had been under his observation for eighteen years, during the whole of which time there were facial irritability and recurrent attacks of tetany. The tetany must be regarded as secondary, for deficiency in blood calcium could not account for any excitability of sympathetic nerve endings and, consequently, spasm of striated muscle. Special stress was laid upon anal spasm as a not uncommon cause of obstinate constipation in infants, and one in which digital stretching of the internal anal sphincter was a completely successful treatment. In the urinary tract functional obstruction might occur in the urethra, resulting in dilatation and hypertrophy of the bladder and ureters, in the ureter, causing dilatation and hypertrophy of a ureter and the corresponding renal pelvis, and at the utero-pelvic junction, giving rise to congenital hydronephrosis. Infantile pylorospasm was then mentioned and regarded as coming within the same category, while congenital hypotrophic stenosis of the pylorus was defined as a congenital abnormality with added spasm, the spasm alone not being sufficient to explain the degree of hypertrophy met with, though it was responsible for the symptoms. Discussing the etiology of the various disorders dealt with he referred to the differing explanations of "achalasia" and spasm, and the arguments which had been advanced in favour of each. It could not be denied that there was spasm at the anus or in the rectum in cases of idiopathic dilatation of the colon where the dilatation and hypertrophy reached down to those levels, for the finger was tightly gripped. Similarly in the bladder cases, the catheter was gripped by the urethra. The bone of contention was a small one—namely, whether the obstruction was provided by a zone of muscle in normal tone or in hypertonia. In oesophagectasis and in Hirschsprung's disease inflammatory changes leading to destruction of Auerbach's plexus had been described, but it was difficult to understand how a paralytic lesion could lead to hypertrophy down to the zone of stricture or how so much hypertrophy could result from obstruction imposed by a zone of muscle in normal tone. Other difficulties in accepting this explanation as the solution in all cases were the incidence at birth or in very early life in some of them, the variability in the degree of obstruction and the periods of freedom from symptoms, the occasional sudden onset of the symptoms as the result of mental disturbance, the permanent relief in some cases by stretching and the freedom from symptoms produced in others by simple persuasion. There was also the positive evidence of gripping by the enema which was vouched for by some surgeons. If the rectal, anal, and urethral obstructions without organic change were legitimately included as belonging to the same group, there was also the definite gripping of the finger or the catheter

CLINICAL SOCIETY OF BATH

A MEETING of the Clinical Society of Bath was held on December 7th at the Royal United Hospital, with the president Mr A. DE V. BLATHWAY in the chair.

Dr WATERHOUSE read a short paper giving an account of five females and one male of ages ranging from 47 to 70 suffering from pernicious anaemia. In each one response to treatment by liver had been rapid and satisfactory. In one patient a red cell count of 1,150,000 with haemoglobin 26 per cent rose

at the end of six weeks to 3,430,000 and 50 per cent, and nine months later to 6,000,000 and 90 per cent, though a few megalocytes were still present. One patient experienced rapid and marked relief of distressing paraesthesia of the limbs. Complete achlorhydria was present in all the patients (four) to whom test meals were given, and was known to have been present in another thirty years previously. A history of sore tongue was obtained from four patients, and in one of these it had been severe enough to prevent the taking of solid food. Three of the patients complained of loss of flesh. In only one was the spleen enlarged.

Dr VINCENT COATES showed a case which he considered to be one of nigryia. There had been silver medication of the eyes. This diagnosis was criticized on the score of the marked localization of the pigmentation to the hands and the conjunctivae, and also because the pigmentation of the hand resembled rather that caused by sunlight than the shade of pigmentation usually seen in cases of nigryia.

Mr MONTAGNE showed a case of marked thickening of the bones of the skull in a young woman. There was a history of the removal under local anaesthesia of a cyst from the upper and outer side of the right orbit, which Mr Miles Atkinson thought had probably been a meningocele. The question of intracranial abscess was discussed, and, in view of the doubtful Wassermann reaction, Dr Waterhouse suggested a provocative dose of no arsenobillon and further blood examination. On account of the severe headache complained of, and the apparent smallness of the pituitary fossa in the x-ray photograph, Dr Thomson suggested a sugar tolerance test.

Dr WATERHOUSE showed a case of stomatitis which had resisted all forms of treatment for many months. Beyond the fact that the eosinophils were markedly increased there were no evidences of a constitutional cause. It was thought to be possibly of dental origin and the red vulcanite of the patient's denture was under suspicion.

Dr DELICATI showed a case of onychotrophic lateral sclerosis with bullar paronychia. As the Wassermann reaction was positive, Dr GONDON thought that the case might probably improve under antisyphilitic treatment.

Dr DUPONT and DOUGLAS MITCHELL and Mr J. S. LEWIS also showed cases.

Reviews.

ERYTHEMA NODOSUM

In a monograph of seventy-two pages Dr J. ODIER SYMES, consulting physician to Bristol General Hospital, summarizes the results of a thirty years' study of 250 cases of *Erythema Nodosum*. He states that in the past this affection has often been described simply as a skin disease, and has been neglected in textbooks of general medicine. Now it is being regarded more and more as a constitutional malady, and possibly even as a separate and specific disease.

Certain interesting facts regarding the incidence of the malady are brought out clearly. There is a definite sex incidence, females preponderating over males in the ratio of over 3 to 1. Most cases occur about puberty or in young adults, but no age is exempt. More cases occur during March and April than at any other time. Definite outbreaks have frequently been noted, the largest referred to by Symes being one of fifty cases in an urban district of Wales in a period of five weeks during August and September, 1920, there having been no previous cases in the area for fifteen years. The incubation period is indefinite, but seems to vary from eight to twelve days. The initial symptoms, before the characteristic nodal rash appears on the limbs, are very variable, but tonsillitis is by far the commonest complaint. The characteristic nodes appear first as bright red spots on the extensor surfaces of the legs and forearms, and come out in successive crops at intervals of three or four days. As they fade they change in colour like a bruise, and may be followed by desquamation. Pyrexia is usually always present, and lasts for a fortnight or longer. Joint symptoms are uncommon. Second attacks of the disease are rare, but one case is quoted in which seven distinct attacks occurred between the ages of 18 and 37 years. The belief that the disease is associated in some way with acute rheumatism dates apparently from a paper

¹ *Erythema Nodosum*. By J. Odier Symes, M.D. Bristol: J. Wright and Sons Ltd. London: Simpkin Marshall Ltd. 1928. (Cr. 8vo pp. 72 8 figures 5s. net.)

by Stephen McKenzie, and according to Symes this view has simply been copied from one textbook to another without any additional evidence. All of Symes's own records and observations, which he tabulates on page 44 of his monograph, are entirely against the view of a rheumatic etiology, or even of a frequent association of the two diseases.

The most important clinical part of the monograph deals with the possibility of a connexion between erythema nodosum and tuberculosis. The evidence is very incomplete, and consists chiefly of indirect observations such as close contact of cases of erythema nodosum with sufferers from active tuberculosis, and the development of tuberculosis within a few months after an attack. Direct evidence is lacking, and, in nodes which have been excised and examined, both histologically and by guinea pig inoculation, almost all the results have been negative. The results of tests such as the von Pirquet reaction in adults can be discounted, and there is really not a shred of evidence in favour of the view often suggested that erythema nodosum is a tuberculous bacillæmia. Symes gives his own observations, founded on a study of 102 cases. In 19 cases tuberculosis was present, in 11 at the time of the attack, in 8 a short time after convalescence. Symes admits that this proportion is by no means high, but nevertheless he feels positive that there is some connexion between erythema nodosum and tuberculosis. He does not consider that the malady is definitely due to tuberculosis, or (as has also been suggested) that it is the exanthem or first allergic sign of a developing tuberculosis. So strongly, however, does the author, from his long clinical observations, hold that there is some definite although subtle connexion between erythema nodosum and tuberculosis, that he recommends that all possible steps should be taken to increase the patient's resistance to tuberculous invasion for six months after an attack.

Information which must be new to most clinicians will be found in the account of the histological examination of the lesion of erythema nodosum, carried out by Professor Geoffrey Hadfield, and illustrated by excellent microphotographs. The lesion is shown to be essentially an inflammation of the small arterioles in the subcutaneous fat, resulting in localized necrosis of the fat. Giant cells appear in later stages which act as fat-phagocytes, and the appearances are really not unlike (although this is not remarked on) those of a subcutaneous rheumatic nodule. No evidence was found in favour of a tuberculous infection, and the conclusion was reached that the emulsion of some soluble toxin gave the best explanation of the lesion.

The last word on erythema nodosum has not been written in this carefully compiled monograph. The author has obviously devoted more time to the study of this disease than any of his contemporaries, and his opinion that a subtle connexion exists between erythema nodosum and tuberculosis must be respected and acted upon. Yet so many cases occur in the absence, before, during, and after the attack, of any other known disease that the possibility of erythema nodosum being an acute specific exanthematous disease, independent of all other diseases, must still be kept for investigation and experiment. With this view there is no doubt that Dr Odery Symes would agree.

CHEMISTRY IN RELATION TO MEDICINE

Recent Advances in Chemistry in Relation to Medical Practice,² by Dr McKIM MURRIOTT, will be found very useful by all students or graduates of medicine who desire to keep in touch with the rapid developments in biochemistry—a task that is difficult for all except specialists in this subject. As the author remarks, “So rapidly has the science advanced that much of the recent chemical literature is likely to be unintelligible to the medical graduate of a few years ago. Yet so important are the applications of chemistry to clinical medicine that a knowledge of recent chemical advances is almost essential to modern practice.” The book consists of six lectures, and

deals with the following topics: acidosis and alkalosis, the chemistry of the blood, food and metabolism, and the endocrines. In handling this material the author has turned to good account his gift for expounding clearly and shortly difficult biochemical problems. The size of the volume, which only contains 140 pages, prevents any attempt at exhaustive treatment of the subjects dealt with, but the author explains the fundamental principle of each and indicates the practical problems of disease to which these principles can be applied. The chapters on acidosis and alkalosis, and on the general principles of diet, are particularly good. The chapters on vitamins and endocrines suffer somewhat from compression. The author has, however, succeeded in his attempt to give a general survey of new work in medical chemistry that can be easily read and understood by those possessing a general knowledge of physiology, and the volume can be recommended to the many members of the medical profession who wish to keep abreast of recent developments in medicine, but who have had little special training in biochemistry.

HAAB'S ATLAS OF OPHTHALMOSCOPY

HAAB'S atlas of fundus drawings of the eye has been known to a succession of students, and has been valued. It was a comfortably small book, and so slipped into the coat pocket with ease. It presented a large number of fair sized fundus drawings of a somewhat diagrammatized order, so that they were more obvious and characteristic of the description of the lesions they purported to represent than anything we ever saw or could expect to see in the human eye. But they served their purpose. Once we had succeeded in seeing what our teachers said was to be seen in such and such a case, once the new world revealed by the ophthalmoscope was fairly entered, Haab's atlas became a useful notebook wherewith to revive impressions, and the impressions did not suffer by the crude realism of the drawings, for we had seen the real thing.

Now Haab's atlas has been reprinted by a society of sight testing opticians, the British Optical Association. Its form has changed, it is no longer a convenient pocket-book, it is a portentous and heavy volume. Yet it is the same Haab, or at least the pictures are the same as in the old edition, only now each small page of the original is gummed into a larger page of this optician's edition. The change in the environment of Haab's drawing is rather suggestive of a change in the uses to which the book may be turned. It is so large that it may bulk in the eyes of its owners to the exclusion of the real thing which to anyone outside the instruction of a genuine hospital for the reception of cases of disease of all kinds is almost certain to happen, they will see so little of the real that the simulacrum must make their world. An unreal “knowledge” of the appearances of disease in the fundus of the human eye will be only too readily obtained by any student of such a book who possesses an eye for form and for colour. He could memorize the series of illustrations and reproduce them at will with pencil and brush, and as easily “spot” another drawing of a fundus condition, since all drawings of the kind are subject to the same limitations of unreality, and yet the successful spotter may be scarcely able to see a fundus with the ophthalmoscope, much less to make any useful diagnosis from his examination of the eye. These are the facts of experience, and not suppositions. When, therefore, we read in the preface to this new edition, “It is earnestly hoped that the present edition will prove equally valuable to the optician of the future, who is now studying the technique of the examination of vision in such a way that he should be superior to his predecessors,” we cannot but fear the coming of a generation of opticians whose knowledge is derived from the copy and not from life, with results that have been too often illustrated in the decadence of an art or a science.

² *Recent Advances in Chemistry in Relation to Medical Practice*. By W. McKim Murriott, B.Sc., M.D. London: H. Kimpton, 1928. (6 x 8½ pp. 141, 12 figures + 10s. 6d. net.)

³ *An Atlas of Ophthalmoscopy*. By Dr O. Haab, Professor of Ophthalmology, University of Zurich. Translated and edited by W. B. Barlow, Fellow of the British Optical Association and published by this association at Clifford's Inn Hall, London, E.C.4, 1928. (6½ x 9½ pp. 230, 87 figures + 21s. net.)

GUY'S HOSPITAL REPORTS

THE last quarterly instalment of the *Guy's Hospital Reports* for the year differs somewhat from its usual character, for there are two long papers occupying two-thirds of the space, and then fourteen cases of interest reported from 'Clinical,' this sixth series being drawn from the first quarter of the year when the Editor and Dr Poulton were the physicians in charge. Dr J B Hance's article on malaria as an independent etiological factor in portal cirrhosis of the liver is based on twenty cases of cirrhosis observed in the North-West Frontier of India, in which other causes—for example, kala-azar—were eliminated. In his article of fifty three pages on hypochondria, its definition and nosology, and psychopathology, Dr R D Gillespie, physician for psychological medicine, first gives a historical sketch of the use of this word, and discusses the clinical criteria necessary to regard a condition as hypochondriacal; these are 'a mental pre-occupation with a real or supposititious physical or mental disorder, a discrepancy between the degree of pre-occupation and the grounds for it so that the former is far in excess of what is justified, and an affective condition best characterized as interest with conviction and consequent concern, and with indifference to the opinion to the environment, including irresponsiveness to persuasion.' Among the cases from 'Clinical' there are four of gastric haemorrhage due to the haemorrhagic diathesis, four cases recorded by Dr E M B West—namely, submucosal haemorrhage, subarachnoid haemorrhage, possible coronary embolism in a man aged 25, and haemolytic non-Addisonian anaemia with Hunterian glossitis and achlorhydria. The evidence against pernicious anaemia in the last case was the low colour index, the unusual profusion of normoblasts, and the type of the Price-Jones curve. A case diagnosed as splenic artery aneurysm, on the grounds that the left-sided pain is unusual in abdominal aneurysm and that the attacks were produced by taking food, is briefly recorded by Mr T G Scott. Very rapidly fatal suppurative syncope due to streptococcal septicaemia is described by Mr D Ellis, Dr Pitt-Rivers gives an account with skiagrams of transposition of the viscera with tuberculous pleurisy, and Mr L Graff a case of congenital cerebral aneurysm which lapsed on three occasions before the final fatal rupture into the substance of the brain. In the commentary it is pointed out that the *post-mortem* appearances of intracranial aneurysm were first described by Sir W Gull in 1859, and the clinical diagnosis by Dr C P Symonds in 1923.

BOOKS ON BACTERIOLOGY

SOME of our readers will be glad to have their attention drawn to recent arrivals in the steady stream of textbooks of bacteriology reaching us from across the Atlantic, even though we can only find space for a few sentences of comment. *The Physiology and Biochemistry of Bacteria* by R E BUCHANAN and E I FULMER, is a compilation and systematization of material relating to the physiology of micro-organisms, particularly of the bacteria, yeasts, and moulds. Students whose interest in bacteriology is purely medical might find this volume useful for reference on some special occasion, but will not need it in routine work. *An Elementary Text-Book of Microbiology*,¹ by WARD GILTSNER, is a good book for science students of bacteriology who wish to have an introduction to all the applications of bacteriological science. In this country it might be of interest to teachers for the D.P.H., but not to medical students. *Elementary Bacteriology*,² by J E and ETHELYN O'NEILL, is a book which we might recommend to satisfy the curiosity of educated laymen about what bacteria are and what they do. Its perusal, however, is a task not to be entered on lightly, and the book is evidently written for the serious-minded student.

NOTES ON BOOKS

The Human Body, by Dr LOGAN CLENDENING, is a work of some originality, treating of the anatomy, physiology and pathology of the body on unconventional lines. It is dedicated to a medical friend with whom the author had many a time sat in into the night and discussed pathological specimens temporarily secreted in their bath tubs, to the horror of their wives. From such gatherings the book, with its breezy conversational style, appears to have had its origin. As a text book of medicine it may not be rated very highly, but the author exhibits considerable erudition, and quotations abound, ranging from Hippocrates to G B Shaw, interspersed with anecdotes having reference mainly to the circumstances of early discoveries. Thus we are shown Vesalius in the dead of night cutting down his first skeleton from a gibbet outside the walls of Louvain, a figure of the fattest woman on record, an engraving of Alexis St Martin's gastric fistula, the title page of the book which first described the action of Epsom salts—a landmark in the history of mankind—a picture of old Aesculapian testing the contents of his wine cask by tapping it, from which his son deduced the method of percussion, and of Laennec watching boys at play, from whom he gained the idea of auscultation. These, with many anecdotes, such as that of the old Shropshire woman who cured the Dean of Brasenose of his dropsy by means of an infusion of foxglove, are to be found on almost every page. The following will give some indication of the author's style. The Princess Caroline (There never was a clever woman who was not a quack,' some scoffers observed) persuaded George I to pardon six condemned criminals who would submit to inoculation for purposes of punishment, all of whom thus escaped hanging, and after a mild case of small pox were free to pursue their customary vocations and avocations. In France Louis XVI was inoculated in 1774, and Marie Antoinette's milliner, Mlle Rose Bertin, in honour of the occasion, designed a special head dress, which was shaped like a small pox pustule, the royal patient was protected from small pox but he was not so successful as the English experimental animals from Newgate in escaping judicial extinction.

The well got up facsimile of *The Ordinal of Alchemy*, by Thomas Norton of Bristol,* reproduced from the copy of ELIAS ASHMOLE'S *Theatrum Chemicum Britannicum* (1652) in the Science Library of Clifton College, is introduced by a scholarly account of its history by Dr E J HOLVIAARD. Thomas Norton, whose father was Mayor of Bristol in 1413, studied alchemy early in life, and when 23 years old thought that he knew how to prepare the Elixir of Gold, he wrote two other works—*De Transmutatione Metallorum* and *De Liquidis Philosophicis*—which, however, were not published. Ashmole, in his annotations on the *Ordinal* (reproduced like the text in the original form), points out that the author's name and residence are revealed by taking the first word of the Proem and the initial letters of six following chapters, which provide the words Thomas Norton of Bristol.

The third volume of *Fortschritte der Sexualwissenschaft und Psychoanalyse*,¹⁰ of which the second appeared over two years ago (see *Journal*, January 16th, 1926, p 107), has recently been issued by Dr WILHELM STEKEL, assisted by Drs ANTON MESSRIEGLER and EMIL GUTHIEL. The volume contains seven original articles, including papers by the editor on the progress of dream interpretation and the psychology of self repression, and the psycho-analysis and forensic significance of kleptomania by Dr Mark Friedemann, nine shorter communications dealing with various aspects of psychoanalysis, abstracts from current literature, and notes on books.

The sixth volume of *Scientific Reports from the Institute for Infectious Diseases*,¹¹ at Tokyo, edited, like the previous issue (see *Journal*, April 7th, 1928, p 600), by Dr YONEJI MIYAKAWA, contains 53 papers, of which 32 are in English, 16 in German, and 3 in Esperanto, devoted to bacteriology, serology, pathology, biology, biochemistry, clinical medicine, parasitology and protozoology, and medical entomology. The subjects discussed include the Wassermann reaction in tuberculosis and leprosy, experimental nephritis, the origin of the oestrous hormone, the sanocrysin treatment of tuberculosis, culture media for spirochaetes, and prophylaxis of Weil's disease.

SATURDAY, DECEMBER 29TH, 1928

MENTAL HYGIENE

From its inception five years ago the National Council for Mental Hygiene has chosen as its special task the building up of an enlightened public opinion in relation to mental disorder. The council seeks to improve the mental health of the community, and to this end it endeavours to combat the prevailing ignorance and superstition regarding the true nature of mental disorder which so seriously hamper the work of those concerned with the treatment of the mentally afflicted. It aims further, at securing a more important position for psychiatry in the medical curriculum, and a closer association between psychiatry and general medicine. Recognizing that factors both hereditary and environmental are responsible for the production of criminality, degeneracy, vagrancy, delinquency, and prostitution, the council, in its fifth annual report¹ maintains that these social evils can be effectively combated only if the relative significance and the mode of operation of the causative factors are adequately understood. Accordingly it proposes (1) to promote a critical study of the social habits, industrial life, and environments of the people, with a view to cradicking those factors which lead to mental ill health and unhappiness; (2) to investigate the various causes physical and psychological underlying failures of social adjustment; (3) to consider the extent to which clinical psychology may contribute towards the elucidation of the problems of habitual criminality, and, (4) from the standpoint of prophylaxis most important of all to study the mental hygiene of child life in relation to education and parental responsibility. Even with the knowledge now available it holds that the mental health of the community could be materially improved in three ways: by the establishment of special clinics and out-patient departments for the early treatment of mental disorder; by raising the standard of care and treatment in the public mental hospitals, and by removing legal formalities which tend to postpone the effective treatment of early cases.

The council's report on the early treatment of persons suffering from functional nervous disorders and minor mental maladies, as it might affect general hospitals is of special interest in view of the proposal of the Ministry of Health's Local Government Bill (1928) to transfer the responsibility for Poor Law administration from the existing authorities to the councils of counties and of county boroughs. This transfer of powers—if full benefit is to be gained from the reforms—should lead to the immediate allocation of a large number of hospital beds throughout the country, and hence it is especially important that administrative schemes relating to the use of available hospital and institutional accommodation should be precisely formulated. The Local Government Bill it will be noted, deliberately excludes the Lunacy Acts from the scope of its proposals, on the ground that these will be dealt with separately in pursuance of the report of the Royal Commission on Lunacy Law and Administration. Such exclusion however will not affect the type of case with which the National Council of Mental Hygiene is especially

concerned. At present there is but scanty provision for the institutional treatment of cases of incipient mental disorder. A questionnaire sent out by the Council to 155 general hospitals in Great Britain and Ireland, as to the facilities at present available for early treatment, elicited the information that not a single provincial general hospital has such in-patient accommodation, though many of them, when necessary, admit patients from out-patient psychiatric clinics to the general wards. Otherwise institutional treatment is not available until a case has become certifiable, and is in a condition to be removed to a special mental hospital. The council proposes in the course of the next few months, to devote itself to a campaign for bringing the needs of early mental and nervous patients to the attention of the councils of counties and of county boroughs. It holds that special departments of the institutions taken over by these authorities can, and should, be allocated for the treatment of these patients. Meanwhile the council has considered proposals for future legislation in relation to provisional treatment orders, the reception of patients who are being treated under any form of provisional order outside of institutions, the notification of borderland cases and of other persons who do not require restriction of their liberty, the adequate protection of the medical practitioner exercising his duties under the lunacy laws, and the after-care of mental patients.

Recognizing that the social inadequacy which results in the production of the unemployable, of the nervous invalid and of the mentally unbalanced may often be traced to the operation of noxious psychological influences in childhood, the council advocates wholeheartedly the extension of a child guidance movement in this country. A memorandum dealing with this problem, and published as an appendix to the report, is particularly opportune at a moment when the first large and fully equipped child guidance clinic is being established in London. Finally, the council realizing that there is no instruction in mental deficiency available for medical practitioners unable to leave their practices to attend a special course has arranged with the Fellowship of Medicine and Post Graduate Association to institute such a course, and to include it in the ordinary post graduate programme.

INTERNATIONAL PUBLIC HEALTH PROBLEMS

THE Office International d'Hygiène Publique has lately issued in pamphlet form a short summary of the proceedings of its Permanent Committee at the last session of that body in Paris in October. This plan of publishing a succinct account of the deliberations of the committee, and so enabling interested persons and bodies to maintain contact with its business has we think, much to commend it as an alternative to the more common practice, particularly among international bodies, of waiting until full verbatim reports are prepared before presenting the tale of their actions to the public.

At this meeting Great Britain was represented by Sir George Buchanan. British India by Colonel J. D. Graham. Australia by Dr C. L. Park, Canada by Dr H. B. Jeffs. New Zealand by Colonel S. P. James, South Africa by Dr P. G. Stock, and the Irish Free State by Dr Boyd Barrett. Representatives of about thirty other States and Dominions were present and in addition Dr Abt, director of the Office International. Dr Rajchman, medical director of the League of

¹ Fifth Report of the National Council for Mental Hygiene (Incorporated) 1927-28 London: 78 Chandos House, Palmer Street, S.W.1

Nations Health Organization, and the late Major C P Thomson, president of the Egyptian Sanitary Maritime and Quarantine Board, took part in the discussions. The special commission, consisting of the delegates of countries interested in the sanitary control of the Mecca pilgrimage, has been established as a permanent body, charged with the duty of examining all information about the pilgrimage each year, and of studying questions bearing upon its sanitary control. A report by this commission, embodying recommendations designed to secure co-ordination in this control, was approved by the committee. It has been decided to publish next year the first issue of an international maritime health annual, giving a comprehensive survey of port sanitary and quarantine administration. In the meanwhile, the encirculation of information relating to ports adequately equipped to carry out "decontamination," and therefore competent to issue the appropriate certificates, is being undertaken. The committee has also been engaged in an effort to abolish unnecessary consular visas on such certificates and on bills of health.

Other matters which have received consideration include the use of wireless telegraphy for quarantine purposes, the utility of rat guards, and the measures of sanitary defence which may usefully be taken in connexion with air traffic from infected countries. A valuable discussion was devoted to the recrudescence of yellow fever in various parts of Africa and in South America since 1926. Reference was made to the Anglo-French conference at Dakar in April last and to the agreement recently made between the Belgian Congo and Angola as examples of international co-operation which should be extended for the defence of Africa against yellow fever, in order, while lessening the possibility of the spread of infection to reduce to a minimum interference with international traffic. The Office International has established a commission to study the question, and it was urged that the health authorities in East Africa, in British India, and in the Far East should exercise the utmost vigilance to prevent the advance in the future of yellow fever in Asia. A variety of other epidemic diseases came under review, including cholera and dengue, and the discussions on post-vaccinal encephalitis, leprosy, the etiology of poliomyelitis, certain aspects of tuberculosis, infant mortality, and other subjects yielded much interesting matter of practical importance to world hygiene.

A NATURAL RESERVOIR FOR MANSON'S BILHARZIASIS

In various parts of Africa and South America, as well as in the Far East, we have found three species of blood flukes—the bilharzia worms—which in the endemic regions are exceedingly dangerous human parasites. The Far Eastern species, in addition to man, lives in a great variety of other mammalian hosts, domestic as well as wild. The African species, however, if we except a possible record from a monkey of what may have been *Schistosoma haematobium*, has not hitherto been found in any animal other than man. It is true that Professor Leiper was able experimentally to infect African and Indian monkeys as well as a variety of rodents, but until now man has been regarded as its sole natural host. In the current number of the *Journal of Hygiene* Dr. T. W. M. Cameron of the London School of Hygiene and Tropical Medicine, who has just returned from a research expedition to the Lesser Antilles, records the natural occurrence of *Schistosoma mansoni* in monkeys in St. Kitts. Curiously enough the monkeys there, and in several of the other islands, are of African origin, and were imported as pets many years ago. During

some of the frequent wars with the French the monkeys escaped to the hills, and there, with no natural enemies, prospered abundantly, and have now become, not only great pests to the planters through their natural predilection for destroying everything they cannot eat, but serious menaces to the health of the community. The relationship of monkeys and man is becoming more and more obvious as time goes by, and one by one the various diseases thought to be peculiar to man are appearing in his more humble relations. In recent years yellow fever has been transferred to Indian monkeys, and adequate research has thus been rendered possible. Now African bilharziasis has been added to the list, while Voronoff has found the monkey a valuable donor in his human rejuvenating work. We are approaching, in fact, a more rational conception of man's true place in the animal kingdom, and this new humility prepares the way for an understanding of much that had hitherto been obscure. The appearance of a reservoir host for *Schistosoma mansoni*—a possibility seen by Leiper twelve years ago, when he elucidated the life-history of these flukes in Egypt—has, however, other and more far-reaching implications. Various schemes for the eradication of bilharziasis in Africa have been mooted, but all fall into one of two classes—eradication in some way of the snail intermediary, or eradication of the adult parasites by the injection of drugs. The second plan, apart from various practical difficulties in its execution, postulates the absence of a reservoir host. The finding of one species of African reservoir host therefore shows that the adoption of such a plan is fraught with hitherto unsuspected pitfalls. It is more than probable that research will bring to light other such hosts in Africa, and, as Leiper pointed out in 1915, the ease with which rodents may be infected in the laboratory suggests that such reservoir hosts may not be confined to the primates. Accordingly, until the absence of such an animal in any locality is established, and until it is clear that such an animal cannot in the future enter the locality, eradication of schistosomiasis by treatment alone has very doubtful chances of success. The eradication of the snail intermediaries, however, strikes at a factor common to man and animals, in the absence of which infection is impossible. The methods of eradication employed—drainage, chemicals, rotations, and so on—will depend on local circumstances, but this method has obviously a much greater chance of success than one which neglects the presence of the parasite in wild animals.

THE PARATYPHOID OUTBREAK IN LONDON

A REPORT was made to the London County Council on December 18th on the serious outbreak of paratyphoid fever which occurred in London and adjacent districts last July. The first information received, on July 30th, was of 5 cases in a southern district of the county. On the following day further cases north of the river were notified. Immediate inquiry brought to light a number of other cases in the western area of London, and simultaneously the Council's attention was directed by the Ministry of Health to cases in adjoining districts outside the county. Action was at once taken, and the outbreak was speedily localized and stemmed. The number of London cases investigated was 282, of which 201 were identified as cases of paratyphoid B fever, 4 of these proved fatal. A report with statistics and full information on the cases has been submitted by Dr. J. A. H. Brincker, senior medical officer. The Public Health Committee records its appreciation of the ability and unremitting labour given to the conduct of the investigations, and of the close co-operation between the Council's officers, the Ministry of Health, and the medical officers of health of the districts concerned, without which the outbreak could not have been dealt with efficiently. The committee adds a brief reference to the question of prevention.

tives in food. The use of preservatives, including boric acid, in food is prohibited in the Public Health (Preservatives, etc., in Food) Regulations, 1925, which came into force in their entirety on July 1st, 1928. "The use of boric acid in food," says the committee, "is intended merely as a preservative and not as a germicide, even in considerably greater strengths than that formerly used; it has no germicidal action on disease-producing bacteria generally, and entire organisms in particular. Although the regulations of 1925 were at first regarded with misgiving by traders, it is now being increasingly recognized that preservatives are not necessary in good wholesome food, and that their presence in food is not beneficial to the consumer and may even be injurious, not only by their effect on the digestive system, but by concealing the unsoundness of food intended for sale. Proper care in the preparation and handling of food to minimize the risk of contamination, and the added safeguard of proper cooking, pasteurization, or sterilization, where applicable, constitute the best means of ensuring a sound and wholesome food supply."

"GO TO THE ANT"

PROFESSOR FOREL'S *Social World of the Ants*,¹ a translation of which by C. K. Ogden, the editor of *Psyche*, is now published, besides being a very fine treatise on the anatomy and physiology of ants, their species and geographical distribution, and their social organization, has the special advantage of being the work of an expert psychologist. It therefore contains a very able analysis of the sensory organs and functions and of the psychology of these insects, so far as it is possible to deduce it from a study of their behaviour, from this analysis the author shows that the characteristic form and perfection of social organization among ants follows as a natural corollary. The book is much more than a work on a branch of natural history, although considered in that light alone it is a very fine work. It is a study in sociology as well, and is rendered all the more interesting by a highly instructive comparison which the author draws between the ant society and human society. Professor Forel has taken an interest in ants from childhood, and his book contains the results of seventy years or more of uninterrupted study of their ways. He considers that the anatomical facts observed justify the opinion that ants possess nervous centres corresponding in a limited degree to our cerebral hemispheres, and that they are known to have the power of communicating their ideas by means of a primitive form of language, expressed by movements of their antennae. It is, then, not surprising that, in a community all of whose members appear to work together for good, acts which we should regard as virtuous are sometimes observed. It is difficult to interpret in any other way the following circumstance: an ant, seeing a friend in danger, endeavoured by gentle persuasion, such as pulling her limb, to entice her away, but, finding her entreaties unavailing, she finally seized her companion and carried her bodily into a place of safety. On the other hand, if ants can claim to possess some of our personal virtues, we must confess that we fall very far short of them in our appreciation of social duties. Every call for the performance of a social duty is immediately responded to by the ants, and the task is executed with efficiency: a breach in a wall brings the builders immediately on the scene, and the military will turn out should there be any danger of the workers being interrupted by enemies from without. The same promptitude and efficiency are observable in every detail of the social economy, and, what is particularly noticeable, the work is done spontaneously, without orders from anyone, the community is purely

anarchical. It would seem that so perfect a system might with advantage be adopted by ourselves, thus, however, Professor Forel shows to be a delusion—human and ant phylogeny have developed along different lines. The circumstances of their history through the centuries have resulted in the memory storage of ideas advantageous to the species in the case of the ants, and their actions are controlled by the instincts so acquired. The phylogenetic history of man is different, when he "came down from the tree tops some millions of years ago, he entered into conflict with the monstrous mammals of the Tertiary period, a time when force was the only law. Thus the primitive man learned to wage war upon other living creatures, including his fellow men. Courage, strength, and cunning were his prerogative"—in other words, his proclivities were individual, not social. Forel represents the matter, hypothetically, in mathematical terms: 60 per cent of more of man's actions, he suggests, may be considered to depend on his individual memory—on impressions acquired during his life-time—the rest being due to hereditary dispositions, while in ants 94 per cent of thought, will, and action may be attributed to species memory or instinct, hence their predominantly social disposition. "The hereditary social instincts of ants permit them to live without chieftains, guides, police, or laws, in an admirably co-ordinated state of anarchy, human beings are absolutely incapable of doing this, and if they attempt as much they at once fall back into such a triumphant state of bigandage that they are compelled to submit once more to the rule of chieftains." Such is Professor Forel's conclusion, it may be hoped, however, that man may in time develop an ideal of concord, and that the corresponding disposition may be transmitted. "Go to the ant—consider her ways and be wise."

LENTICULAR DEGENERATION IN INFANTS

PROGRESSIVE lenticular degeneration, described by S. A. Kinnier Wilson in 1912, has been found from time to time in children, and the onset of the disease when met with in adults may sometimes be traced back to childhood. T. H. H. and L. Harbitz have, however, carried the disease back much further in a recent paper,¹ where they describe a case of lenticular degeneration in an infant aged 8 months. The parents were first cousins, and two other children had died from convulsions in early infancy. There was no history of any nervous disease in the parents' families. The infant suffered from convulsions during the second week of life, and, according to the mother, had always lain very quiet in bed, hardly ever kicking, it had not lifted up its head or sat up. On admission to hospital there was considerable rigidity in the flexor muscles of the arms and in the abductors of the legs. The reflexes were brisk, and the plantar responses were both flexor. The pupils were equally large, and reacted to light. The day after admission the infant developed twitchings of various muscles in the four limbs. Lumbar puncture showed clear fluid, not under pressure, with 6 cells per c. mm. normal sugar, and no increase in protein. The infant died next day, with convulsions and a continuance of the twitchings. At the necropsy there was no obvious evidence of any disease on the surface of the brain, but, on section, the outer third of the lenticular nucleus on both sides was found to be porous, softened, and honeycombed, this was also well marked in the putamen and pallidum. The caudate nucleus and internal capsule were normal in appearance. Microscopical examination confirmed the fact that these degenerative changes were almost entirely limited to the region of the lenticular nucleus. The liver in this case was not abnormal. Here, at any rate, there seems to be clear evidence of a young infant with lenticular degeneration, but further striking confirmation was found

¹ *The Social World of the Ants*. By Auguste Forel. Translated by C. K. Ogden. In two volumes. London and New York: C. P. Putnam's Son, Ltd. 1928. (i) pp. 311, Vol. I, pp. xxx + 551. 25 figures, 9 plates. Vol. II, pp. xiv + 445. 42 figures, 14 plates. £3 3s. the two volumes.)

¹ *Acta Paediatrica*, viii, August 1928, p. 112.

in the fact that a previously born sister had died from convulsions on the fourth day of life, with marked degenerative changes in the neighbourhood of the right internal capsule and lenticular nucleus, and with no other change except oedema in the rest of the brain. The familial nature and the situation of the lesions in these cases make it very probable that they were examples of Wilson's disease. The absence of changes in the liver may possibly be explained by the very early age at which death occurred. The presence of curious twitchings not associated for the most part with any definite convulsions, and the rigidity without an extensor plantar reflex, seem to point to involvement of the extrapyramidal system. It is possible that careful examination of the basal ganglia of infants dying from convulsions with unusual clinical findings such as described in this case may lead to the discovery of changes in the lenticular nucleus, and confirm the occurrence of Wilson's disease at an early age.

THE NEEDS OF THE BLIND

THE necessity for increased support for the organizations which minister so devotedly to the needs of the blind is revealed in the annual reports for the year 1927-28 both of the National Institute for the Blind and of St Dunstan's, which provides for the care of blinded ex-service men. Subscriptions, donations, and the proceeds of collections received by the National Institute showed a further drop of nearly £10,000, following a decline of £15,000 in the previous year, while the expenditure of St Dunstan's was almost £5,500 in excess of receipts. It is unnecessary to give in detail any account of the activities of these bodies, both of which are widely known, although apparently suffering from an insufficient realization of their financial needs. The National Institute, which has the distinction of being the largest institution of its kind in the world, has played an extremely important part in developing the publication of embossed books, periodicals, and music in Braille and Moon type for the blind—a service of incalculable value. Particular attention is being paid to the requirements of students, and a special library has been formed for their benefit. Homes, hostels, and colleges are maintained, training is provided in a variety of callings, assistance is given in the form of grants and pensions, in securing employment, in the marketing of goods, and in a score of other ways. In recent years the Institute has become of increasing importance as a co-ordinating centre for the numerous local societies. The report, richly illustrated with photographs, gives an exceedingly interesting account of its multitudinous activities which should attract attention to its work and should, it is to be hoped, provoke a substantial inflow of money to its coffers. St Dunstan's, within the narrower limits of its own province, works along similar lines, its main preoccupation having been, in the thirteen years of its existence, the training and re-establishment of men blinded in the war. Those who have come under its care deserve especially the best aid the public can afford by reason of the circumstances in which they lost their sight, their training presents a special problem through the tragic fact that blindness came when they had already attained manhood. The work of St Dunstan's does not cease during the lifetime of its subjects, for the after-care department continues to provide advice and assistance for all who have passed through the establishment. There are further, many ex-service men whose sight has since the armistice, faded gradually through causes attributable to the war, nearly 900 such cases have already been added to the roll of St Dunstan's men, and to-day there are over 1,900 men—with dependants numbering almost 5,000—under the care of the institution. During the year the main establishment for the personal care of blinded men was removed to Brighton, the headquarters

remaining in London. The photograph given in the report to illustrate the progress achieved by men who have gone forth to take up an independent existence once more bears witness to the success achieved by St Dunstan's in rebuilding shattered lives. We trust that both these admirable institutions will speedily gain wider support from the public, who can assist most usefully by subscribing liberally to their funds, and also by purchasing goods manufactured in their workshops or made by blind craftsmen trading on their own behalf.

ELECTROCUTION IN THE X-RAY ROOM

A CASE is reported in which a child aged 8, while undergoing x-ray examination, was killed by an electric shock. At the inquest it was stated that a fluorescent screen was used, and three examinations were made during the third of these a nurse and the mother, standing on opposite sides of the x-ray couch, were holding the patient. The doctor, having completed his examination, was walking across the darkened room to switch on the lights when there was a sudden flash near the floor, the nurse was stricken unconscious, the mother was "lifted off the ground" and fell on the floor, and the child was found to be unconscious and suffering from burns on the forehead and limbs. Artificial respiration was applied to the child, but without avail. The mother and nurse recovered without any serious effects. The doctor felt a shock when he lifted the child off the table. It appeared from the evidence given at the inquest that the nurse had only once before been in the x-ray room, and having no idea of possible risks, was standing in the "danger zone," close to the high-tension leads which passed from overhead down under the couch, and close to a foot-switch controlling the current supply. The radiologist stated that he had no doubt that she was in such a position as to form an electric circuit from the high-tension leads through the child, and that this was the cause of the accident. He added that there was no practical method available for insulating the high-tension leads of the apparatus. The jury returned a verdict of "accidental death," and attributed no blame to anyone. The coroner said that the question of admitting inexperienced persons to the x-ray room might be considered by the hospital authorities concerned. This case raises several questions of importance. The dangers arising from electric currents, especially of high tension, have long been recognized, and, in so far as the public may be exposed to them, form the subject of legislation. There are, for instance, very stringent regulations about protecting the public against accidental contact with electric cables in the streets, while the Factory Acts provide for the efficient fencing of electrical machinery in factories and workshops. The wiring of premises for distribution of current from public supply mains is also carefully supervised, in order to minimize risks of fire and electric shock. There seems, however, to be very little control over the manufacture or sale of electrical appliances so as to ensure that these shall be reasonably safe for the purposes for which they are intended. Naturally the makers and vendors of such apparatus are sufficiently jealous of their reputation to take such precautions as they deem sufficient, but these may not be enough to render their products "fool proof." The dangers arising from excessive exposure to x-rays are now so widely known that nearly all x-ray tubes are provided with efficient devices for shielding the operator from the rays. In this matter the National Physical Laboratory has issued instructions which no manufacturer would venture to disregard. There is, however, a good deal yet to be done in the way of protecting the high-tension circuits used. When it is remembered that death has followed exposure to a current of only 50 volts, while the "secondary circuit" of an x-ray

apparatus carries a current of from 50,000 up to 250,000 volts, the danger of electrocution becomes obvious. As was stated at the request in this unfortunate case, it is not necessary to touch the wires, etc., carrying such a high potential—mere proximity will allow a dangerous electric discharge to take place from the conductor to the individual who approaches within a few inches of it, and when, as is usually the case, an x-ray screen examination is made in a room plunged almost into complete darkness, it is clearly necessary to provide that, as far as can be arranged, it shall be physically impossible for anyone present to receive a shock from the apparatus. The best apparatus undoubtedly fulfils these requirements, the whole of the high tension circuit being enclosed, either in some non-conducting material, or in some kind of cage which allows adequate inspection without involuntary palpation of the dangerous parts of the plant. There will, of course, always remain the human element, and ignorance or carelessness will claim an occasional victim. The only remedy for this lies in education. In this connexion it is, perhaps, not out of place to call attention to a rather dangerous kind of suggestion which is now being made by some manufacturers of electro-medical apparatus. These firms, in their advertising, let it be supposed that by the use of their x-ray apparatus any person without previous training can produce radiograms of the highest excellence, and set up as an expert radiologist. The suggestion that there is nothing to be learnt about x-rays will, it is hoped, not be taken too seriously.

MEDICAL EDUCATION IN SOUTH WALES

ALTHOUGH it is too early for optimism there appears now to be some prospect of ending the unhappy conflict between the Cardiff Royal Infirmary and the University College of South Wales, which has interrupted in some measure the clinical teaching of Cardiff students and has led to withdrawal by the English Conjoint Board of its recognition of the medical school. With a view to bridging the gap between the two contending parties a draft scheme of co-operation, which has been approved by the honorary medical staff of the Infirmary, is now to be considered by the council of the College. Provision is made for meeting the cost of structural alterations or additions to the hospital buildings, which may be necessary in the interests of both institutions, and for the payment of grants to the hospital in respect of special services rendered in connexion with the medical school. Beds are to be allotted in a definite proportion to the professors of medicine, surgery, and gynaecology, who would thus become honorary members of the hospital staff, and arrangements are outlined for representation of each institution on the council of the other, and on any joint standing committees set up in accordance with the supplemental charter of the University of Wales. It is proposed to establish a board of clinical studies to organize the clinical teaching at the Infirmary. This would be composed of all the recognized clinical teachers and part-time lecturers who are members of the honorary medical staff of the Infirmary, the professors of medicine, surgery, obstetrics and gynaecology, and pathology, the radiologist, and the lecturer in anaesthetics, one member of this board is to be appointed to represent it on the Board of Medicine. It remains to be seen whether the necessarily divergent points of view of the Royal Infirmary and of University College can be completely reconciled on such lines, even after modification, but the scheme may at any rate be welcomed as indicating a desire to examine as fully as possible the ways by which co-operation might be restored. The end of this long controversy will be applauded by none more readily than by the many members of the British Medical Association who enjoyed the hospitality of Cardiff at the last Annual Meeting. All will hope for a wise settlement of

old disagreements, and the defining of a basis of permanent harmony, which is vital to the cause of medical education in South Wales.

PROFESSOR MAX NEUBURGER

THE issue of the *Wiener medizinische Wochenschrift* for December 8th was devoted to the history of medicine, in honour of the sixtieth birthday of Professor Max Neuburger, who holds the chair of the history of medicine in the University of Vienna. Professor Neuburger is the corresponding member for Austria of the Osler Club, and on December 7th this club celebrated his birthday in a Malpighi evening. Dr J. D. Rolleston spoke of Neuburger as a medical historian, and emphasized the wide range of subjects covered by his pen, referring especially to his neurological studies and his papers on medical Vienna in bygone days. With this tribute Sir D'Arcy Power associated himself. Messages were received from the Austrian Minister in London and from Professor Arturo Castiglioni of Padua, the corresponding member for Italy. An exhibition of Professor Neuburger's most important works had been arranged. Papers on Malpighi, illustrated by slides and exhibits, were read by Professor W. E. Le Gros Clark and Dr J. B. Pulton. The Wellcome Historical Medical Museum had lent their portrait of Malpighi for the evening. The meeting was closed with a charming little speech by Dr A. P. Cawadas.

THE annual congress of the Ophthalmological Society of the United Kingdom will be held in London on April 11th, 12th, and 13th, 1929. Two general discussions will be held: the first, on "Heterophoria," to be opened by Mr F. Maddox, Group Captain Cecil Clements, and Mr Charles Coulson, and the second, on "The diagnosis and treatment of ocular tuberculosis," to be opened by Sir Arnold Lawson, Dr R. A. Young, and Mr S. A. Browning. Members who wish to take part in the discussions or propose to read papers should communicate with Mr M. H. Whiting, 51, Wimpole Street, W. 1.

THE Home Secretary has appointed Sir Arthur Keith, M.D., F.R.S., to be a member of the Advisory Committee on the Administration of the Cruelty to Animals Act, 1876, in succession to the late Sir Hugh Anderson, M.D., F.R.S.

THE KING'S ILLNESS

RECENT news from Buckingham Palace seems to have given the public a feeling of quiet confidence. The medical communiqué printed in our last issue at page 1151, and widely reproduced in the press, achieved its purpose. With more precise knowledge of the facts of the case doctors were able to form a better estimate of the probable course of the King's illness, and to help others towards a more composed frame of mind. The long bulletin issued on December 20th, after a comprehensive joint survey of the position, was equally opportune, and its tone of guarded hopefulness did much to steady opinion. Since then there has been little of moment to record. The fact that during Christmas week very brief bulletins have appeared at longer intervals than usual speaks for itself. We may reasonably infer that His Majesty, though not out of danger, is making as much progress as can be expected at this stage of his uphill journey. He has far to travel yet, and there may be further checks, but some ground has evidently been gained in the past ten days. Thus the indications so far as they go, are favourable.

Nova et Vetera.

THE HISTORY AND LORE OF CINCHONA.

BY

C J S THOMPSON, M.B.E.

"THIS medicine, the most precious of all those known in the Art of Healing, is one of the greatest conquests made by man over the vegetable kingdom" These words were written of cinchona by Lambert over a century ago, and his judgement on this invaluable drug is fully borne out to day. The mass of material dealing with the history of cinchona is so great that it is possible to give only a brief outline of it within the limits of a paper. For this purpose, therefore, it will be well to consider it from three aspects in its development during the past three hundred years—namely, the traditional, the empirical, and the chemical.

Although much has been written concerning the early history of the drug, our knowledge of the precise date when its remedial properties were first discovered, and of the manner of that discovery, is largely traditional, and is still enveloped in mystery. A picturesque story is related by Geoffroy of an Indian who, having lost himself in the dense forests of Peru, became stricken with fever, and at length collapsed from exhaustion beside a little lake. He drank eagerly of the water, into which a cinchona tree had fallen, and awoke, after a troubled sleep, to find that the fever had left him. There is, however, no foundation for this legend, which was not recorded until late in the eighteenth century. The same may be said of the tradition related by La Condamine in 1738, that the schifuge properties of the bark were discovered by the natives through watching the punas chew it in order to cure their fevers. As a matter of fact, the aborigines of South America, with the exception perhaps of the tribes in the neighbourhood of Loja, appear to have been quite ignorant of its medicinal virtues. Markham observes that it is also significant that the medicine bags or wallets carried by the native itinerant doctors, whose *materia medica* had been handed down from the time of the Incas, never contained cinchona bark.

Although Peru was discovered in 1513, and had submitted to the Spanish by 1550, no mention has been found of the bark earlier than the beginning of the seventeenth century. Joseph de Jussieu, who visited Loja in 1739, believed that the first knowledge of the properties of cinchona was derived by the Indians of Malacotas, some leagues south of Loja, a town founded by the Spaniards in 1546. He states that the use of the drug was first made known to a Jesuit missionary who, when suffering from an attack of intermittent fever, was cured by the bark, which was administered to him by an Indian chief at Malacotas in 1600, and La Condamine claims to have discovered a manuscript in the library of a convent at Loja in which it is stated that the Europeans of the province used cinchona about the same time. A similar story is related of Don Lopez do Canizares, the Spanish Corregidor of Loja, who is said to have been cured of fever by taking the bark in 1630. The fact, however, that its local name was "quina-quina," which means "bark of birds," seems to indicate that some special value was attached to it.

It is somewhat remarkable that, although the Indians of Peru strongly adhere to their traditional customs, they made no use of cinchona medicinally and even in more recent times actually had a prejudice against it in many

cases. 'Pobppig, writing in 1830,' says that 'the people of Huancua, who frequently suffer from tertian agues, have a strong repugnance to its use, while Humboldt declares that at Loja the natives would rather die than have recourse to what they consider so dangerous a remedy. Spruce makes a similar observation with regard to the people of Ecuador and Colombia, and says it was difficult to make the natives believe that their red bark could be required for any purpose other than for dyeing cloth.'

The first authenticated record of the therapeutic value of cinchona is in the year 1638, when the wife of Don Luis Gerónimo Fernandez de Cabrera, Bohrdilla y Mendoza, fourth Count of Chinchon and Viceroy of Peru, was stricken with intermittent fever in the palace of Lima. This lady's maiden name was Ana do Osorio, and she was the daughter of a noble family whose founder was created Marquis of Astorga by Henry IV, King of Castile. At the age of 16 she was espoused to Don Luis do Velasco, a grandson of the first Marquis of Salinas, who died within four years of their marriage.

The young widow, who was a woman of great beauty, became lady-in-waiting to Queen Margaret, wife of Philip III, and while at court she married for the second time. Her new husband was the Count of Chinchon, who was Lord of the Castle of Chinchon near Madrid, and of eighteen towns in the kingdom of Toledo. The count was appointed Viceroy of Peru in 1628, and with his countess made solemn entry into Lima on January 14th, 1629. When the news that the countess was suffering from fever reached Don Francisco Lopez do Canizares, the Corregidor of Loja (who had himself been cured of an attack by means of the drug), he at once dispatched a packet of the powdered bark to Dr Juan de Vega, physician to the countess, assuming him of its efficacy in the treatment of "tertiana." De Vega decided to give it to his patient, with the result that the countess made a rapid and complete recovery.

According to a manuscript by Hipolito Ruiz, the particular species from which the bark administered to the countess was taken was that known to the bark collectors of the time as—"Cascarilla de Chahuarguana," which abounds in cinchonidine. Howard points out the interesting fact that it was therefore to this particular alkaloid that the countess owed her cure. After her recovery the countess became an enthusiastic advocate of the remedy, and caused quantities of the bark to be collected, which she not only administered to her dependants, but distributed to those suffering from fever. Thus it came to be called the "countess's powder."

Hanbury declares that the bark was certainly known in Spain in 1639, a year before the countess returned to Europe, as on that date it was administered for the first time to a priest at Alcalá de Henares near Madrid. The countess came back to Spain in the spring of 1640, and brought with her a quantity of the bark, with the intention of distributing it among those suffering from fever on her husband's estate, where tertian fever was very common. When Dr Juan de Vega followed her, shortly afterwards, he brought with him a further supply, which it is said he sold at Seville for 100 reals a pound.

Little more is known of the bark until 1653, when Chifflet, physician to the Archduke Leopold of Austria and Governor of the Low Countries, wrote a report on the drug and its introduction into Europe. He says "Among the wonders of the day many reckon the tree growing in the Kingdom of Peru called Lignum Februm, whose virtues chiefly reside in the bark, which is known as China Tobris. During the last few years it has been imported into Spain, and thence sent to the Jesuit, Cardinal Joannes de Lugo at Rome."

THE COUNTESS OF CHINCHON
(From an alabaster effigy on her tomb)

In 1652 Chifflet's master, the Archduke, had been taken ill with fever and was treated with the bark, but although he recovered from two attacks he refused to take it in a subsequent one, to which he succumbed. The physicians of the time were divided in their opinions as to its value. Considerable controversy arose, and although it was admitted by many that it palliated the fever they insisted that it "fixed the humour," thus causing a relapse of some other dangerous disease.

Roland Sturm, a doctor of Louvain, who wrote a treatise on the new febrile in 1659, states that it was known in Brussels and Antwerp at that time as "pulvis Jesuiticus," because the Jesuit fathers used to administer it. They charged the rich the price of its weight in gold, but gave it to the poor who suffered from quotidian fever. It was more commonly known as "pulvis Peruanus" or "Peruvianum febriifugum." The fathers in Peru sent considerable supplies of the bark to Rome, and the methods of using it were explained to a congress of Jesuits assembled in that city. It was afterwards distributed to members of the community by Cardinal de Lugo, the Procurator General of the Order, who also gave it away to the poor who came to his palace. Thus it became commonly known in Rome as the "Cardinal's bark," or the "powder of the Fathers." Sturm states that he "saw twenty doses sent to Paris in 1656 which cost 60 florins and according to directions issued to the apothecaries of Rome for its administration it was to be given infused in white wine. Cardinal de Lugo, on visiting Paris found Louis XIV. suffering from an attack of intermittent fever and persuaded him to take the bark, after which he made a good recovery.

In spite of its success in such notable cases however, its medicinal value still remained a subject of dispute. Chifflet in Paris in 1653, and Plempius of Rome in 1656 both predicted the disappearance of the bark as a therapeutic agent and denounced its use as harmful, on the other hand, Badus of Genoa, in 1655, defended it and quoted 12,000 cures by its aid in Italy alone. The high price it commanded caused many worthless substitutes to be sold, and the Spanish merchants were charged with sending various other stringent barks into Italy, adulterated with aloes, to give them a better taste.

The bark does not appear to have been known in England until about 1655, the first mention of it occurring in the *Mercurius Politicus*, one of our earliest newspapers in 1658, a year in which an epidemic of remittent fever raged in this country. It is referred to as "The excellent powder known by the name of the Jesuit Powder brought over by James Thomson, a merchant of Antwerp." Brady, then professor of physic at Cambridge was one of the first to prescribe it, and Willis observes it as coming into daily use, but its general introduction seems to have been largely due to Robert Talbot, who may be said to have made his name and fortune by exploiting it as a secret remedy.

Robert Talbot, or Talbot as he was sometimes called, had a remarkable and interesting career. He was born in 1642 and after leaving school was apprenticed to Mr. Dear, an apothecary of Cambridge. Although entered as a sizar at St. John's College for five years, there is no evidence that he ever graduated. About 1671 he settled in Essex to practise medicine, where, he says, "I planted myself near the seaside where agues are the epidemical diseases." In the following year he published a little book called *Pyretologia, a rational account of the cause and cure of Agues*, in which he makes reference to his secret remedy for the fever, and states that it consisted of four ingredients, "two indigenous and two exotic." He alludes to Peruvian bark as follows:

'Let me advise the world to beware of palliative cures and especially of that known as Jesuit Powder as it is given by unskilful hands. Yet this powder is not altogether to be condemned for it is a noble and safe medicine and if rightly prepared and corrected and administered by a skilful hand other wise as pernicious a medicine as can be taken.'

Talbot's reputation soon increased, and he removed to London, where he set up his sign next door to Gray's Inn Gate in Holborn. The results of his treatment brought him rapid success and after having cured the daughter of

Lady Mordant of an attack of fever, he was summoned to Windsor to see Charles II, who had been seized with the same complaint. He was fortunate in being able to restore the King to health, and so secured the royal favour. Talbot was not a licentiate of the College of Physicians and had no qualification to practise, so, to save him from attacks from that quarter, the King caused a letter to be written to the College, restraining that body from interfering with him in his practice in London. On July 27th, 1672, he was appointed physician to the King, and later on received the honour of knighthood at Whitehall. By a patent issued under the Privy Seal dated August 7th, 1678, Sir Robert Talbot was granted an annuity of £100, together with the profits and privileges appertaining to a Physician-in-Ordinary to the Sovereign. Evelyn, in his diary, on August 22th, 1679, states that he had

'conferred with the Marquis of Normandy concerning the Quinquina which the physicians would not give the King at a time when he was in a dangerous ague. It was the only thing that could cure him (out of envy, because it had been brought into vogue by Mr. Talbot, an Apothecary) until Mr. Short to whom the King sent to know his opinion of it privately sent word to the King that it was the only thing that could save his life and then the King enjoined the physicians to give it to him, which they did and he recovered.'

From this it would appear that the active ingredient in Talbot's remedy was more than suspected at that time.

In 1679 Talbot visited Spain, and on his return through France stayed for some time in Paris, where he soon became a prominent personage. Madame de Sévigné alludes to him several times in her "Letters," and remarks "Nothing is talked of here but the Englishman and his cures." In November, 1680, when the Dauphin was seized with an attack of fever, Talbot, who had made influential friends at the French Court, was called in and undertook to treat him. Madame de Sévigné says, "the King, Louis XIV., insisted on Talbot preparing his wine in his presence before giving it to the Prince." The treatment was eminently successful and the Dauphin soon recovered. Talbot was made a Chevalier, but the King, determined to learn his secret, eventually induced him, for a sum of 2,000 louis d'or and an annuity of 2,000 livres, to reveal his method of treatment and the formula for his remedy, which, however, is not to be published until after his death.

After a further visit to Spain, where he cured the Queen of an attack of fever, Talbot returned to London, where he died shortly afterwards, in 1681 at the early age of 40. He was buried in Trinity Church, Cambridge.

The formula for his remedy was published in England in 1682 under the title *The English Remedy or Talbot's wonderful Secret for curing of Agues and Fevers*. According to this book he used several preparations of the bark. The first consisted of a strong infusion of the bark with a decoction of aniseed and juice of parsley, and after a day or two as much claret wine was to be added. This was allowed to stand for eight days and the liquid then strained off. He then made an infusion with the residue of the first one with equal parts of fresh bark in powder. This was again macerated with more claret for ten days, and, after being strained, formed the wine he generally administered. He also used a tincture, which he made by macerating two ounces of Peruvian bark in eight ounces of spirit of wine for fifteen days. It is interesting to note that this preparation is practically the same strength as the tincture of cinchona of the British Pharmacopoeia to-day. To it he would sometimes add red roses, lemon juice, fennel-root juice, smallage leaves, or parsley, and, when he thought necessary, a small quantity of tincture of opium. These were the preparations of cinchona, all excellent of their kind, by means of which Talbot became famous throughout Europe.

During the last illness of Charles II the bark was again administered to him twice. According to the record, on February 5th, 1684,

His physicians hearing that a species of intermittent fever was raging all over the city which commenced with severe convulsions but which was speedily cured by the use of Peruvian bark at intervals they all agreed to administer it to the King and draughts were prepared of the bark in powder with Syrup of Cloves and given in small doses throughout the day.

There is an interesting bill in the British Museum, dated 1675, in which Dr Charles Goodal offers to sell at the "Coach and Horses" in the Physicians College in Warwick Lane—

"a superfine sort of Jesuits bark ready powdered and papered into doses at 4s per ounce or £3 per pound, and for the excellency and efficacy of this particular Bark enquire of Dr Morton in Grey Friars

The same price for Jesuit's bark is quoted by Gideon Harvey in a list of drugs dated 1678

"When in the hands of the Jesuits" (says the author of the "English Remedy") "it was sold in Rome for 8 or 9s the dose which consisted of two drachms. Three or four years ago the best might be had for 40s the pound. Sir R. Lalor observing that Febrifuges were prepared which came very near his own, and fearing that least somebody at length might discover it resolved to buy up all the Quina-quina that he could find in Paris and the chief towns of England and France—a wise proceeding on his part

About 1675 Peruvian bark was accepted into the domain of regular medicine, and in 1677 it first appeared officially in the *London Pharmacopoeia* under the name of "Cortex Peruanus"

With reference to the preparations of the drug, mention should be made of Dr John Huxham, who was the originator of the well-known compound tincture of cinchona, the formula for which he published in his *Essay on Fevers* in 1755, and which was first included in the *London Pharmacopoeia* of 1788

We are indebted to the French for the early botanical studies on cinchona. The first attempt to transport any plants to Europe was made by La Condamine in 1743. He was assisted in his pioneer investigations in Peru by Joseph de Jussieu, who, after fifteen years of laborious work, was robbed of his valuable collection of plants, a circumstance which so affected him that he lost his reason.

In 1742 Linnaeus established the genus *Cinchona*, and in 1753 first described the species *Cinchona officinalis*, which he so named in honour of the Countess of Chinchou.

The reckless manner in which the natives of Peru collected the bark at this time, often destroying the trees, while making no attempt to plant new ones, suggested that there would soon be a shortage of the valuable drug. This possibility aroused attention in Europe, and prompted serious efforts to cultivate the tree on a large scale in countries where the climatic conditions were suitable. In 1839 Royle strongly advocated the introduction of cinchona into India, and after a long delay this was carried out through the efforts of Sir Clements Markham, but not, however, before the Dutch had commenced the cultivation of the trees in Java.

The success which attended the latter enterprise was chiefly due to Charles Ledger, a Londoner born in Bucklebury, whose story is not without an element of romance. After travelling in South America in the employment of the New South Wales Government buying alpacas, he succeeded in obtaining, through a native servant, some seeds of the *Cinchona calisaya* from Bolivia. Owing to the jealousy of the natives, who became enraged, he was afterwards so ill-treated that he died from the effects. Ledger sent the seeds to his brother in England, who first offered them to the British Government, but the offer was not entertained. He then sold half of them to a Ceylon planter, and the remainder to the Dutch Government for about £33. From these seeds 20,000 plants were raised in Java, and so the great industry, from which millions of money have since been made, was founded.

Until the beginning of the nineteenth century cinchona bark was still used in its crude state, although several unavailing attempts had been made to discover its active principles. It was not until 1810 that Gomez of Lisbon succeeded in unlocking the secrets of the bark and isolated its basic properties, which he called "cinchonine." A few years later Pelletier and Caventon, the French chemists, set out to study the whole chemistry of cinchona, and in 1820 they were able to prove that the "cinchonine" consisted of two distinct alkaloids, one of which they called "quinine" and the other "cinchonine." The next advance was made by Henry and Delondre, who in 1833 isolated quinine. This was followed by the discovery of cinchonidine by Winckler in 1844, while Pasteur produced the alkaloidal derivatives cinchonidine and quinine.

Since the discovery of quinine thirty alkaloids have been found to occur naturally in cinchona barks, and from these there have been many derivatives. Quinine, the most important of the cinchona bases, possesses the most powerful febrifuge properties of all, and is capable of completely neutralizing acids and forming crystallizable salts.

The sulphate, at one time so largely employed in medicine, is now being superseded to some extent by the more soluble salts, such as the disulphate, the hydrochloride, and the dihydrobromide, all of which are much more soluble in water.

Thus briefly in outline is the history of cinchona, a drug that has proved of inestimable value to mankind, and one that has provided the medical practitioner with the most effective and reliable weapon in his armamentarium, for the treatment of malarial and intermittent fevers.

MEDICAL MEMBERS OF LOCAL PUBLIC BODIES

The following list, containing the names of medical practitioners known to be serving as members of local authorities or their subsidiary public bodies in Great Britain, is supplementary to that published in the *Journal* of December 8th (p. 1057). Information relating to about 120 authorities is embodied in the two lists, the number of medical members mentioned being considerably more. In a substantial proportion of cases the office of mayor or its equivalent is held by a medical practitioner. The presence of medical men on public bodies—especially in the case of county and county borough councils—assumes a greater degree of importance at the present time than ever before, in view of the fact that the Local Government Bills now before Parliament introduce important changes in the administration of the Poor Law and of health services, and charge the larger authorities with the formulation of detailed schemes for the reorganization of this work in their areas. It is therefore desirable that contact should be established and maintained between medical practitioners associated with local bodies and their colleagues in order that the views of the profession may receive adequate representation and full consideration in the drawing up of administrative schemes under the bills.

ENGLAND AND WALES

COUNTY COUNCILS

Cheshire—Sir William Hodgson, Crewe (Alderman and Chairman, Chairman, Joint Sanatorium Committee for Cheshire and Stoke Boroughs). Dr H. D. Brice, Dukinfield, Dr W. I. Fern, Congleton, Dr John Somerville, Macclesfield, Dr Charles Wilson, Crewe.

East Suffolk—Dr H. N. Baron, Orford.

Hertfordshire—Dr J. S. Dockray, Bishop's Stortford Member, Higher Education Subcommittee for Watford, Dr C. Herbert Hall, Watford.

Lancashire—Dr George Scarr, Radcliffe (Chairman Midwives Acts Committee, Member Taberculosis and Public Health Committees). Dr Isaac Flack, Radcliffe.

Middlesex—Co-opted member of the Education Committee. Dr H. B. Brackenbury, Hendon.

COUNTY BOROUGH COUNCILS

Bath—Dr Preston King (Member, Health Committee). Co-opted member of the Maternity and Child Welfare Committee. Dr D. A. Mitchell.

Gloucester—Dr D. E. Finlay (Chairman, Health, etc., Committees, Member, Education Committee).

Leicester—Co-opted member of the Secondary Schools Subcommittee and Medical Services Subcommittee. Dr Astley V. Clarke.

Newcastle on Tyne—Dr G. D. Newton, Dr R. W. Simpson, and Dr J. W. Leach.

Newport (Mon)—Dr J. Lloyd Davies (Alderman), Mr John McGinn, F.R.C.S.I. (Alderman). Dr T. G. Lewis (Alderman).

York—Co-opted members: Maternity and Child Welfare Committee—Mr A. R. Lister F.R.C.S., Special Diseases Subcommittee—Dr G. W. Micklethwait and Dr H. E. H. Reynolds.

NON-COUNTY BOROUGH COUNCILS

Andover—Dr E. A. Farr (Deputy Mayor), Dr C. Edwards.

Hornsey—Dr H. B. Brackenbury, Hendon (Alderman, Member, Education Committee).

Presentation to Professor Priestley Smith

In recognition of his distinguished services to the Queen's Hospital, Birmingham, to which he was for thirty years ophthalmic surgeon, Professor Priestley Smith, LL.D., F.R.C.S., was, on December 14th, presented with his portrait painted by Mr Harold Speed. The presentation was made by Sir Charles Hyde, president of the hospital, who said that, were he preaching a sermon, he would take for his text, "Let us now praise famous men." Priestley Smith was indeed a famous man, not only in Birmingham, but all over the world, his wonderful research work had received many tributes. As long ago as 1878 he was awarded the Jacksonian prize for his essay on glaucoma, in 1890 he received jointly the Middlemore prize of the British Medical Association, in 1898 he was elected Bowman Lecturer of the Ophthalmological Society, the Royal and Imperial Medical Society of Vienna made him an honorary member, he received the first award of the Netteship gold medal, and in 1905 was elected president of the Ophthalmological Society. In 1925 the University of Birmingham conferred on him the honorary degree of LL.D., and two years later he had the great distinction of being awarded the Lucan Howe medal of the American Ophthalmological Society. That was but a short record of his great work, he had lived a long life and a useful life—a life of devotion to his profession and to the service of mankind. It was in 1867, sixty-one years ago, that Priestley Smith entered the Queen's Hospital as a medical student. "His great achievements," Sir Charles Hyde concluded, "are rather like a fairy story, and, like the fancies, he does not appear to grow older and he still bewilders us in the magic circles of research." Professor Priestley Smith, in replying, reviewed the outstanding events of his career and of his work at the Queen's Hospital. He mentioned that before he became a medical student he was apprenticed for four years as a mechanical

engineer. It might be thought that was a bad start, but really it was the best thing that could have happened to him, because he picked up a rough working knowledge of mechanics, and some working knowledge of materials and of drawing. Also, he learned a good deal about the wonderful work which was done by skilled workmen, and about the workmen themselves. These things had been of the greatest benefit to him ever since. In conclusion, he asked the chairman to allow the portrait to become the property of the hospital and to be hung in the board room. Mr W E Adlard, who accepted the gift on behalf of the committee of management, spoke of the great help he had given the hospital apart from his medical work, and Mr B J Waid, chairman of the Medical Committee, said that Professor Priestley Smith was the greatest living authority on certain diseases of the eye, and that his work would live for all time.

Medico-Legal Society

The annual dinner of the Medico-Legal Society was held on December 14th at the Holborn Restaurant. The president, Sir William H Wilcock, in proposing the loyal toast, expressed the respectful and loyal sympathy felt for His Majesty in his trying illness, and admiration for the example set by the Queen and other members of the Royal Family in their fortitude and courage. Dr F G Crookshank, proposing "Medicine and the Law," said that the toast was so important that it was worth while discovering what it meant. Were they toasting medicine and the law, or medicine *versus* the law? Lay persons held strong views about two organisations known to them as the British Medical Council and the General Medical Association. He, on the other hand, was in doubt as to whether one should refer to Sir T R Hughes as Chairman of the General Law Society, or of the Bar Council Association. Sir T R Hughes, in his reply, repudiated any conflict between medicine and law, they were, he said, sister professions, both concerned with their duty to humanity. Medicine watched over the body and soul, law over the character, property, and reputation. The victories of medicine were without a shadow of disappointment. Those of law, however, were won only at the cost of another's loss. The aims and ideals of both professions were frequently misunderstood, both had to do their best work in face of the calumnies of a hard world. Dr Walter Carr said that the Medico-Legal Society was valuable in that it brought men together who were all the better for understanding each other's mentality. The doctor, in tackling his problems, tended to ignore laws and regulations. This could hardly be said of the lawyer. Difficulties naturally arose between professions so different in outlook, and a society which brought both together conferred great benefit on the public. Mr Justice Branson, in proposing the toast of "The Medico-Legal Society," said that everyone present was either a member or a guest. The medical and legal minds were not so completely opposed as Dr Carr had suggested. They both worked on much the same lines, were both engaged in discovering the known from the unknown, and in weighing the evidence of things which could be seen and heard in order to proceed to a knowledge of things which they could neither see nor hear. Responding on behalf of the society, the president said that there were few departments of human endeavour which were not associated in some way with medicine and the law. The society aimed at bringing the two professions into harmony, and, above all, at helping to dispel the suspicion so naturally felt by the doctor for the lawyer who was to cross-examine him. The toast of "The Guests" was given by Mr Justice Humphreys, and was responded to by Sir Leonard Kershaw, Registrar of the Court of Criminal Appeal, and Sir Malcolm Delevingne of the Home Office.

Dinner to Colonel J Graham Martin

On the occasion of his relinquishing the appointment of A.D.M.S., 55th (West Lancashire) Division, which he had held since 1920, Colonel J Graham Martin, M.B., T.D., Honorary Physician to the King, was entertained to dinner on December 13th at Liverpool by past and present officers of the Royal Army Medical Corps, and many others who had served with him before, during, and since the war. Colonel D C Leyland Orton, T.D., who has succeeded Colonel

Martin in his appointment, presided. The 6th Battalion the King's Regiment, to which Colonel Martin was formerly attached as medical officer, was strongly represented. Colonel R. Jackson, T.D., honorary colonel to the R.A.M.C. of the 55th Division, proposing the health of the guest, referred briefly to Colonel Graham Martin's long service, commencing in the South African war and later in France. Colonel J. B. McKaig, D.S.O., T.D., who seconded the toast, said that he had served with Colonel Martin for many years, and recalled several humorous incidents in their service. Colonel Martin, he said, as medical officer of his battalion (6th Battalion the King's Regiment), had become an institution, and was looked upon by all as the kindest and most careful of officers. He was exceedingly glad when Colonel Martin received the honour of K.H.P., and added that recognition had long been due to him for his excellent services at Ypres. The toast was further supported by Major-General H. W. Higginson, C.B., D.S.O., Commander 55th (West Lancashire) Division, and by Colonel J. F. Martin, C.M.G., C.B.E., D.D.M.S. Western Command. Both referred to the fine work which Colonel Martin had done, and spoke of their sorrow at losing him. Colonel Graham Martin then responded to the toast, and expressed his great appreciation of the kindness shown him by all present. He related several amusing incidents in his service, and concluded with a warm reference to the high character of all officers of the regular army with whom he had come in contact.

New Food and Drugs Act

The Food and Drugs (Adulteration) Act, 1928, which repeals and consolidates the provisions of the Sale of Food and Drugs Acts, 1875 to 1927, together with a number of other amending provisions contained in other statutes (notably the Milk and Dairies Consolidation Act, 1915), will come into operation on January 1st. Local authorities are reminded of this fact in a circular (No. 950) issued by the Ministry of Health, in which it is pointed out that the wording of the new Act is not in all respects identical with that of the older statutes. Attention is drawn particularly to the use of the terms "food and drugs authorities" and "sampling officers." The official memorandum as to procedure (Memo. 36/Foods) has been revised, and the Public Health (Preservatives, etc., in Food) Regulations have been printed in a consolidated form. In conclusion, the circular states that the Minister desires food and drugs authorities to continue the practice of sending copies of the public analyst's quarterly reports to the department as soon as they are received, and that, in particular, he hopes that copies of the reports for the fourth quarter of 1928 may be sent before the end of January, 1929. Copies of the circular and the memorandum of procedure (price 1d net each), and of the regulations (price 3d net), may be obtained from H.M. Stationery Office, or through any bookseller.

Annual Reports of Medical Officers of Health

The Minister of Health has issued a circular (No. 939) to local authorities of counties, boroughs (including metropolitan boroughs), and urban and rural districts reminding them of the duty imposed upon their medical officers of health of drawing up an annual report, and specifying the nature of the report to be prepared for 1928 for submission to the authority and to the Minister. Details are given regarding the form and content of the report in appendices to the circular, which also contains an announcement regarding the provision of vital statistics for the various areas by the Registrar-General, and a note on the duty of medical officers of health of district councils in connexion with reports to the Home Office on the administration of the Factory Acts in workshops and workplaces. Among matters which are required to be covered by reports for the first time or in which a substantial alteration has been made is information respecting clinics and treatment centres. Medical officers are instructed to insert the name, situation, and nature of accommodation of maternity and child welfare centres, day nurseries, school, orthopaedic, and artificial light clinics, tuberculosis dispensaries, and venereal disease treatment centres, and to state by whom they are provided. Details are also to be given regarding action taken by local supervising authori-

ties under Acts relating to the registration of maternity and other nursing homes, and additional information respecting water supplies is desired. Reports, farther, should include references to any arrangements made for the publication of information or dissemination of knowledge relating to health or disease, to action taken in connexion with food adulteration, and to the existence of, and nature of the work done at, any laboratories for the clinical and bacteriological examination of food. Particulars should be given of the prevalence of any animal or insect pests, and of the measures taken for their suppression, and also of any action taken for the prevention of blindness. It is stated that application is often made by individual medical officers of health to the Registrar-General for the figures of cancer, tuberculosis, and maternal mortality rates in England and Wales as a whole for inclusion in their reports, arrangements have therefore been made for the publication of these figures in the Registrar-General's weekly returns as soon as the necessary data are available.

Scotland.

Heredity and Disease

A LECTURE was delivered under the auspices of the Combe Trust on December 12th in Edinburgh by Professor F. A. E. Clew. Lord Sands presided. The lecturer asked his audience the question, Why do living things become ill or grow old and die? and suggested as answers that ill health and death were relatively new phenomena and were not inherent adjuncts of life, but only appeared because highly specialized tissues and functions had emerged in the course of evolution. The duration of life, the healthiness of the individual life, and the cause and time of death were determined by the combined action of heredity and environment. For each individual there was a specific duration of life, predetermined by the inherited constitution, and modifiable only within relatively narrow limits. The chief effect of environmental forces was to determine the rate at which the inherited endowment was used up. There were some five hundred or more abnormal states, defects, or derangements which could be transmitted from parent to offspring in an orderly fashion, of these many could be cured by the physician and surgeon, but it was better not to have them. Half of the patients in hospitals were the victims of ignorance and carelessness, others were persons who had inherited the seeds of disease, and who were doomed from the beginning, until the way to repair a poor inheritance should be discovered. Why, he asked, did an insurance company display a peculiar interest in the relatives of one about to be insured, and inquire how old these were when they died? It was because they knew the real recipe for a long life. This was not, as commonly suggested, abstinence in food or drink, or tobacco, or work, or play, for if one wished to live until one was 100 the secret was to be born into a family in which all four grand parents were centenarians. The problem of to-morrow would be largely concerned with the question of what to do with life, for it was probable that the duration of life would be greatly extended. Even now some inherited deficiencies in the endowment of individuals could be repaired by physical and chemical means. The cretin, the diabetic, and the infantile were being restored to health by the supply of what had been deficient. Thyroid extract, insulin, and ultra-violet rays were crude forerunners of a vast armamentarium which mankind would ultimately use for its own repair. As knowledge increased so would man's power grow over his physical environment, and people might remain permanently youthful and healthy.

Edinburgh Crippled Children

The annual meeting of the Edinburgh Crippled and Invalid Children's Aid Society was held on December 11th in Edinburgh. Sir John Findlay presided. The twenty-sixth annual report was submitted and showed that the number of cases treated for the past year had been 728. The majority of these were adolescents whose crippling conditions were more or less confirmed and who sought

help in the difficult problem of employment. With regard to children, it was noted that an increasing number required only temporary help and would, by the time of adolescence, in all probability, no longer be cripples. A number of patients had been provided with various surgical appliances, and some 400 persons were cared for in respect of various surgical, medical, industrial, or social needs. Much attention had been paid to providing work for cripples in their own homes, and it was proposed to appoint a teacher trained in craft work, thus should in time enable each worker to make a small regular income. The total cost of the society's operations for the year had been £4,106. The chairman remarked that the society represented an association of about 100 persons, who were actively and voluntarily engaged in devoting time and talent to the mitigation of disabilities in crippled persons. It was one of the few happy consequences of the war that during the last few years greater attention than before had been devoted to deformities, and the result had been the evolution of methods which twenty years ago were entirely unknown. He trusted that the power now attained would be still further increased. The great need of the present day was not surgery so much as after-care, which was a good deal restricted by lack of opportunity for looking after children subsequently. This work was one of the chief objects of the society. The outlook of the crippled child in Scotland was made brighter by the great scheme which had been recently launched for a large orthopaedic centre in Edinburgh, before long a hospital would be erected.

Presentation to Dr Allan Gray, Leith

To mark the completion by Dr J. Allan Gray of fifty years' practice in the town, the Leith Medical Practitioners' Association recently presented him with a barograph and a cheque to be expended on further gifts. The president, Dr H. G. Langwill, referred to Dr Allan Gray's many activities during his long residence in the town—his tenure of office as physician to Leith Hospital, his pioneer work as lecturer there to women medical students before Edinburgh Royal Infirmary admitted them, his arduous and often difficult duties as medical officer of health of the old burgh (before whole-time service was introduced) in seeking to institute more sanitary measures in the town, his services as examiner in medical jurisprudence and public health for the Royal Colleges, and, not least, his long continued connexion as surgeon to the Volunteer and Territorial Forces in the town, of which he was lieutenant-colonel—all in addition to the constant work of a busy practitioner. Dr Gray, in reply, spoke with feeling, thanking his fellow practitioners for their kind thoughts towards him, and recalling some of the difficulties he had to contend with as a part-time medical officer of health in bygone days.

Correspondence.

ROYAL MEDICAL BENEVOLENT FUND AND GUILD

SIR,—As 1928 closes it is fitting that a short account be given of the work of the Royal Medical Benevolent Fund and the Royal Medical Benevolent Fund Guild.

During this year the Fund has voted no less than 457 grants, amounting to £8,621. This has enabled those beneficiaries to buy food, clothing, and other necessities of life who would otherwise have gone without. The Guild, which is the ladies' branch, supplements the work of the Fund, and has granted from its own funds to cases recommended by the Fund monthly maintenance grants to elderly people amounting to £781, for coal £266, as well as invalid comforts and medical requisites £44, and other relief and maintenance amounting to £1,272.

In a letter it is impossible to give a true picture of individual cases helped, but many widows who have been left penniless have been supported. Boys and girls have been able to continue their education, which otherwise would have ceased at the death of their fathers. The Guild, whose especial care is education, has paid £1,124 in school and training fees, and expenses for forty-two

cases, besides investigating and recommending suitable schools and training centres, and arranging, when necessary, holidays. The visiting and personal service is greatly appreciated by the beneficiaries.

The Fund has also given annuities to 185 persons, amounting to £4,970. These annuitants are chosen from those who have reached the age of 60 and are either widows or medical men who, through illness and old age, have been unable to continue their active duties. The average amount of annuities is £40 per annum, but owing to a recent legacy the Fund has been able to grant six annuities of £100 each.

Both the Fund and the Guild depend entirely on voluntary subscriptions to carry on their work. A subscription of £1 from every member of the medical profession to the Fund and a similar subscription to the Guild from the wife of every medical man would enable the Fund and Guild respectively to carry on and extend their joint work.

The British Medical Association has done much to bring to the notice of medical practitioners the existence and objects of the benevolent fund of the profession, and has also very greatly assisted in collecting subscriptions. In acknowledging this help we appeal to all readers of the *British Medical Journal* to continue as generously as possible the support they have already given in the past, and ask those who have not contributed before to consider in 1929 whether they cannot help us in our work.

The Guild is in urgent need of clothing for men, women, and children. Subscriptions to the Fund should be sent to the Honorary Treasurer, Royal Medical Benevolent Fund, 11, Chandos Street, Cavendish Square, London W 1 and to the Guild, to the Honorary Treasurer, Royal Medical Benevolent Fund Guild, 58, Great Marlborough Street, London, W 1—We are, etc.,

CHARLES J. SYMONDS,
Honorary Treasurer to the Fund
MARY SCHARLIEB,
Honorary Treasurer to the Guild

London Dec 1928

VACCINE TREATMENT OF PUERPERAL SEPSIS

SIR,—The paper by Dr R. R. Armstrong and Mr W. Shaw in the *British Medical Journal* of December 15th (p. 1032) is notable as a methodical attempt to estimate the value of vaccines of a particular kind and given in a particular way to combat puerperal infection. The results of vaccination given in treatment and for prevention of sepsis are not very clearly separated in the conclusions drawn by the writers. It appears, however, that the therapeutic method is declared a failure, and prophylaxis is believed to be of subsidiary importance and to have no demonstrable value. The first conclusion is in accordance with much modern experimental work, which suggests that in treatment vaccines for the most part do not act specifically, and that vigorous measures are needed if non-specific vaccination is to have much effect. The second conclusion seems unnecessarily pessimistic when it is remembered that only a single dose of one kind of vaccine was given, and that vaccine one treated with specific serum—a product which the authors themselves, in agreement with most other workers, declare to be of very doubtful value. The previous history and virulence of the culture used to make the vaccine are not stated, although probably these are of great importance. Sound aseptic technique is no doubt of great and fundamental value, but it is possible that specific prophylaxis may also have a place.

This letter is written with the object of pointing out that prophylactic vaccination, so far from having failed in the cases recorded, can scarcely be said to have been tried, and that a sound method of preventive vaccination deserves further trial on a large scale—I am, etc.,

The Lister Institute London Dec 18th JOSEPH A. ARKWRIGHT

PROPHYLAXIS OF PUERPERAL PYREXIA

SIR,—Will you permit me to make the following brief suggestions in connexion with the above subject. Axiom 1. Prevention is better than cure. Axiom 2. Sepsis is the highest factor in maternal mortality, it is a form of wound infection. Axiom 3. Wound infections go with

difficult labours, the avoidance of which is the principal key to the situation

Under the Puerperal Pyrexia Notification Act consultants have been appointed in many parts of the country to assist in its cure. Why not extend their function to preventive work in the form of ante-natal consultations? Smugly clean inductions in institutions are very safe when compared with difficult forceps cases, and although the judgement of experts in this realm is often faulty (and well it may be, for is there a branch of medicine that requires greater experience?) yet on the whole a fairly high percentage of difficult labours would be avoided. I have been assured that occasional help at the ante-natal clinics in the country over problematical cases would be welcomed—I am, etc.,

London W 1 Dec 6th

F. LAWTON MOSS

BREAST-FEEDING

SIR,—In your issue of December 15th (p. 1085) I notice with great interest the report of a presidential address delivered by Dr. H. W. Pooler to the Midland Branch of the British Medical Association on the subject of breast-feeding.

Dr. Pooler has interested himself in this subject for many years, as evidenced by his contribution to the literature, and from time to time other medical practitioners, obstetricians, paediatricians, and infant welfare workers contribute the results of their experience to the medical press. It is, however, noticeable in all the literature on this subject, whether in textbooks or in original articles, that there are still wide differences of opinion upon the physiology of normal lactation, and that, although considerable figures have been published from time to time, both on the Continent and in America, the work of collecting accurate records has been most sporadic. The chief difficulty in the way of satisfactory milk analyses has been that of extracting the milk from the breast in an entirely natural manner. The child's method of obtaining it is a double action: (1) Compression of the base of the nipple by the gums; (2) Suction action of the tongue and cheeks. Artificially we can only abstract the milk by one or other of the methods—namely, by hand expression or suction pump, but not by the two combined.

Recently Dr. Margaret Lowenfeld and Miss Sibyl Widdows, D.Sc., have been carrying out research work on the composition of normal human milk, first in the obstetric unit of the Royal Free Hospital, under Professor McIlroy, and now in the infant welfare clinic of the children's department at this hospital. Side by side with normal babies they are doing a certain number of abnormal cases—for example, those apparently suffering from fat indigestion—and they are getting some extremely interesting results. It appears, for instance, that although the protein, sugar, and ash percentages differ from mother to mother after the first three weeks, each individual has her own constant in these milk elements, whether the sample be taken before or after nursing early or late in lactation. On the other hand, fat acts quite differently from the other constituents and its percentage varies enormously, according to the time of collection, and—a most important point—according to the method of extraction. Papers have already been published by Dr. Lowenfeld and Miss Widdows,¹ and it is hoped that the work they are now carrying on will throw further light on the subject.

There has hitherto been far too much vague teaching about breast-feeding, and probably too great a tendency to regard human milk as a constant fluid dependent upon the state of nutrition rather than the individuality of the mother. It will be a step in the right direction if these two workers are able to collect some really reliable facts about the physiology of lactation—I am, etc.,

London W 1 Dec. 17th

HAZEL I. CHODAK GREGORY

¹ *Biochemical Journal* 1927 vol. xxi No. 1 p. 1 and *Journal of Obstetrics and Gynaecology of the British Empire* 1928 vol. xxxi No. 1 p. 3.

SO CALLED "WHITE ASPHYXIA" OF THE NEWBORN

SIR,—Mr. Aleck Bourne has performed a real service in calling attention to the treatment of so-called "white asphyxia," and in pointing out that the accepted methods are more likely to damage than assist the child's chances of recovery.

I think there is little doubt that most obstetricians will agree that the "white baby" is suffering from surgical shock and not asphyxia, and it is indeed high time that the term "asphyxia," in this connection, should be eliminated from the textbooks in use by our students and pupil midwives. So long as the words "white asphyxia" occur the student mind turns instinctively to methods of artificial respiration, and the present evil will continue.

Mr. Bourne says that he believes most examiners secretly agree with the teaching that artificial respiration in the case of "white asphyxia" is not only useless, but actually wrong, but teachers equally feel that they must teach artificial respiration in deference to the requirements of the forthcoming examinations. As a teacher and examiner I certainly never require a student to express what is manifestly unsound.

It is sincerely to be hoped that Mr. Bourne's views on this matter will receive the support they deserve and that when any future author feels the spirit move him to write a textbook of obstetrics let the term "white asphyxia" be eliminated and substituted by the correct nomenclature of "foetal shock"—I am, etc.,

BECKWITH WHITEHOUSE, M.S., F.R.C.S.

Birmingham Dec. 17th

SIR,—In his welcome protest against the use of artificial respiration in these cases Mr. Aleck Bourne instances "twilight sleep" babies in a way that may convey the impression that they all suffer from shock and oligopnoea due to being under the influence of morphine, but possibly he refers only to such as are "under the influence of morphine" at birth.

Dr. J. O. Greenwood, writing on amnesic narcosis in Dr. J. S. Fairbairn's *Practitioners' Encyclopedia of Midwifery and the Diseases of Women* (1921 edition), says (p. 789) "records show much less oligopnoea since the use of a second dose of morphine was discontinued."

My own experience of a considerable number of "twilight sleep" cases is that if the morphine is limited to the first injection, and if the dosage of scopalamine is individualized and limited to the production of amnesia (analgesia being avoided), white asphyxia is not common in normal labours; indeed, "twilight sleep" helps to lessen the frequency of this and other complications by rendering unnecessary the use of instruments on account of shock or exhaustion of the mother. When white asphyxia does occur it passes off without artificial respiration, but I have found most "twilight sleep" babies cry lustily as soon as they are born—I am, etc.,

London N.W. 8 Dec. 18th

J. CURNOW PLUMMER

ETHYL CHLORIDE ANAESTHESIA IN TONSIL AND ADENOID OPERATIONS

SIR,—Under the above title in the *British Medical Journal* of December 15th (p. 1113), Mr. Norman Barnett has given his views with regard to the advantages of that anaesthetic for the operations in question. I do not propose to reopen this evergreen topic of discussion, and will only say that for those who require a brief anaesthesia, as for the guillotine operation, ethyl chloride may suffice, whereas others who, like myself, always employ the "dissection" method, a more prolonged narcosis will be necessary—that is, if bleeding is to be effectually controlled before the patient is allowed to leave the operating table.

But it is the apparently light-hearted way in which Mr. Norman Barnett treats the question of haemorrhage which constrains me to join issue with him, for I fear that coming from such an authority the vonnger and less experienced operators may be encouraged to share in his opinion that "a great deal too much stress is laid on the loss of a little blood in these cases" (para. 3). If they should be

so influenced the bag of haemorrhage after tonsillectomy, which many of us have been trying to lay low, will probably take a new lease of life.

If one reads him rightly, I would like to ask Mr Barnett if he seriously contends that the occasional bleeding of "an exceptionally large and rigid vessel" can be safely and securely dealt with during the brief general anaesthesia and post-anaesthetic analgesia induced by ethyl chloride, and that "in the average case a little gauze pressure" will suffice to stop the bleeding effectually.

Furthermore, perhaps he will inform us if "the comparatively long post-anaesthetic analgesia period which succeeds the anaesthetic one" (of ethyl chloride) is sufficiently deep and prolonged to allow, say in the case of a child, for the consummation implied in the last sentence of the third paragraph. "It is always wise to reopen the gag, apply this pressure, and then do any toilet that may be required in the exceptional case."

I hope these are fair questions to ask on the subject of haemorrhage, because in the operation of tonsillectomy, by whatever method it is practised, the minimizing of the chances of post-operative bleeding is one of the chief duties of the surgeon. Its occurrence may be serious for the patient, is always alarming for the relatives, and will not infrequently present difficulties and anxieties to the operator. If such queries appear to be unduly critical it is because an experience of some thirty years has convinced me that unless definite and time-hallowed surgical measures are taken to prevent post-operative haemorrhage, this may occur in an otherwise perfectly executed tonsillectomy.

Even when every precaution has been taken the operator will occasionally have to meet this accident, but it will be a rare one compared with such as are likely to follow the practice of those who trust to less efficient measures, and in this category I should place "a little gauze pressure." Is it not probable that a fit of coughing or the act of vomiting will reopen a vessel so insecurely closed?

Surely there can be only one practically sure method of preventing haemorrhage after tonsillectomy, and that is by ligaturing the two chief arteries which supply the gland—namely, above, the tonsillar branch of the descending palatine, and, below, a branch from the ascending palatine, arteries. Frequently it will suffice to ligature only the first named, and the time required for doing so will often be less than eight to ten seconds.

It has been my practice for the last ten years to adopt this precautionary measure in every case operated upon, and the ages of the patients range from 1 to 72 years. In going through the list of those for whom I have been personally responsible the proportion of post-operative bleeding is just over 1 per cent. Before that period, and when one depended on pressure with gauze swabs, etc., the figure was nearer 10 per cent. It is with the hope that this easy and quickly applied surgical measure for preventing post-operative bleeding after tonsillectomy may be adopted more freely, that I again venture to urge its advantages.

In conclusion, and in opposition to Mr Norman Barnett's statement, it is my opinion that insufficient rather than a great deal too much stress is laid on the loss of a little blood in these cases"—especially if it continues or is "hidden" after the operation is completed—I am, etc.,

London W. Dec 17th.

HERBERT TILLEY

STRANGULATED FEMORAL HERNIA

SIR,—In connexion with the subject of Mr Hamilton Bailey's excellent article (December 8th, p 1033) it has always appeared to me that we require facts of a somewhat different order from those given before we can assess the relative values of the femoral and inguinal routes. The superiority of the inguinal route in strangulated cases is evident though excess of fat may make the operation difficult. We require to know from those who have had a large experience of such work what is the percentage of recurrence in cases of femoral hernia of which the neck of the sac was small and in those of which it was relatively large. When the neck of the sac is small the prognosis after operation by the ordinary femoral route seems to be much better than when it is large. A bad

anaesthesia, by causing the sac to retract, may unfortunately introduce a further variable tending to prevent success and to obscure the elucidation of the problem.

It has never been clear to my mind that our methods can convert what nature ordains as a likely recurrence into a non-recurrence. A comparative test may perhaps be found in a study of the results of the inguinal operation undertaken in the treatment of recurrence following the femoral operation performed in non-strangulated cases. One such case is known to me, and recurrence took place within six months after each operation. The neck of the sac was relatively large, and though the musculature was good the patient was obese—I am, etc.,

DIAGNOSTIC CLINICS FOR CANCER

SIR,—In the *Journal* of December 1st (p 1008) there is a letter from Mr Malcolm Donaldson on the subject of radii and cancer, in which reference is made to the need for diagnostic centres at which cases of cancer might be recognized in their earliest stages, in an editorial article in the same issue (p 999) you comment on the suggestion to the consideration of those concerned with the public health. It may perhaps be of interest to relate what is being done in the city of Leicester, where a cancer diagnostic clinic has been in operation since July of last year.

This clinic, which is officially known as the Cancer Control Clinic, was the outcome of representations made to the Leicester Health Committee by the Leicester Advisory Cancer Committee. Briefly, the arrangements are as follows. The clinic is run by the Leicester Corporation Health Committee with the cordial co-operation of the Leicester Royal Infirmary. It is held one evening a week in consultation rooms at the City Health Offices, and the leading surgeons in the city take it in turns to attend, their services being paid for by the corporation. Before the scheme was started it was submitted to a meeting of medical practitioners in the city, and received their warm approval. They were invited to send to the clinic any suspicious cases where an expert opinion was considered desirable, and, as a matter of fact, many of the patients attending the clinic have come in this way. The clinic has also been made known by advertisement in the press, by notices exhibited in factories and infant welfare centres, and by a notice which is exhibited weekly in all corporation tramcars. Attention has been drawn to its existence by public talks and lectures. It was decided to limit the clinic to women, and, in the first instance, to afflictions of the breast and uterus, the reason for this limitation being that it is in cancer of these two organs that the value of early diagnosis can be most easily demonstrated.

The total number of patients attending during the sixteen months that the clinic has been in operation has been 152, 82 having affections of the breast, 41 having affections of the uterus and allied parts, and 29 having affections of other parts. The cases are dealt with as follows:

1. If they are considered possibly malignant they are usually referred to our Royal Infirmary, by arrangement with this institution such cases are given preferential treatment as regards admission, and are admitted almost immediately—that is, within a few days.
2. If there is no evidence of malignancy the patients are reassured, or in some cases told to report again. No actual treatment is given at the clinic.
3. If thought desirable, cases are referred to their own medical attendant.

Of the 152 cases, 26 were admitted to the Royal Infirmary, and 11 of these definitely proved to be cancer.

The number of patients making use of the clinic is considerably less than could easily be dealt with in the one session a week, and, naturally, we should like to see a larger number of the public availing themselves of the facilities provided. Nevertheless, it is felt that the scheme has justified itself, and there is no intention of abandoning it, especially as there is so little that can be done by a local authority apart from propaganda in connexion with this disease. Incidentally it may be said that the existence of the clinic and the means taken to make it known are

in themselves a very important method of propaganda, bringing home to the public the vital importance of early diagnosis.

The advantage from the patient's point of view of the facilities provided by the clinic as compared with the out-patients' department of a general hospital are that the patient gets individual attention and the best possible advice free of charge, without the long wait among a crowd of other patients, and other drawbacks, which usually obtain in most of such departments. As the public come to realize these advantages it is probable that the clinic will be used more extensively. Indeed, patients are now beginning to come to the clinic on the recommendation of those who have already been there themselves—I am, etc.,

C KILLICK MILLARD,

Leicester Dec. 13th Medical Officer of Health, Honorary Secretary,
Leicester Cancer Committee

PAPULAR URTICARIA

SIR,—Your last three issues contain a good deal of controversial matter on this important subject. Leaving theory aside, the clinical evidence of both general practitioners and specialist is much to be welcomed. It should afford a practical basis for the treatment of these troublesome cases. Dr Rupert Hallam must be congratulated on his observation that residence in hospital alone, without special diet or drugs, is sufficient to clear, at least for a time, the eruption in children. I can confirm his results, but I should like to offer some possible explanations of these apparently strange events.

It is convenient, and probably not unscientific, to regard these vasomotor disturbances as a "habit." This habit appears to be maintained by a number of factors, although some of these only may operate in a given case. These factors include diet, autogenous toxins, physical and mental fatigue, even psychological conditions and external irritation of the skin. I place diet first as the commonest and sometimes the sole determining cause and I am at a loss to understand those who deny this as an agent. It must surely be common experience to find certain foods at fault. The list of these is legion. I have myself seen children who react after banana, as in the case quoted by Dr Bugess, but the offending food is often chocolate, egg, fish, etc., and removal of the offending agent does in most early cases cure the trouble. Hospital diet, it must be allowed, is simpler than in the average home, and is free from those "bit-bits from the table" so common in poorer households. Dr Hallam will pardon me if I suspect that those children who were housed in hospital but fed from home did not really receive a representative home diet. I shall still expect a child who reacts to fish at home to react to it in hospital, and I hope to make the experiment.

For a long time past I have found an essential condition for the cure of a chronic urticaria to be an initial rest, both physical and mental if possible. This is provided in hospital. Finally, there is the question of cleanliness and clothing, apparently small matters, but really of very great importance. My mind goes back to the case of a doctor's child in which a definite cure was only reached after the child was dressed in soft underclothing—not woollen. Relief was then prompt and permanent.

Space forbids my touching on other points, but I will conclude by asserting that many cases of papular urticaria in childhood can be cured by attention to the general health, dieting, cleanliness, and proper clothing. If I had the choice of one drug only it would be iohimbic acid and soda—I am, etc.,

Manchester Dec. 17th

G. H. LANCASHIRE

SIR,—Referring to the recent correspondence on the subject I should like to make it quite clear that I do not suggest that the skin reaction known as urticaria clears up when the patients are removed to hospital. I have admitted many chronic cases for investigation and cannot recall such a happy event. My statement applied only to the so-called papular urticaria—a definite clinical entity which is also known by the name of lichen urticatus and strophulus. Also, I was not including a transient

macular rash sometimes met with in young children, which then grandmothers, with enviable confidence, attribute to the evil effects of teething or to dietetic indiscretion. Papular urticaria was accurately described by Thomas Bateman more than a hundred years ago in the following terms:

"Its first appearance is in irregular inflamed wheals so closely resembling the spots excited by bites of bugs and gnats as almost to deceive the observer. The inflammation however subsides in a day or two leaving small elevated itching papules. When the first wheals are thus terminating, new ones continue to appear in succession until the whole body and limbs are spotted with papules which become here and there confluent in small patches. The eruption is peculiar to children it commences in some cases soon after birth, and sometimes later and continues with great obstinacy for many months. Both the wheals and papules are accompanied with intense itching which is exceedingly severe in the night occasioning an almost total interruption of sleep and considerable loss of flesh."

Mr Frank Coko adds other articles to the long list of foods which, during the last century, have been observed to excite attacks of urticaria. These lists, more or less complete, appear in all textbooks on dermatology, and in my opinion somewhat overshadow the fact that urticaria is not infrequently due to focal sepsis, and also that it may be the initial sign of serious systemic disease.

Again returning to the subject of papular urticaria, I may say that I have tried house dusts with negative results, but I do not regard this as conclusive, and shall still pursue the line Mr Coko kindly suggests.

Dr Bugess, apropos of my ten cases of breast-fed infants suffering from the complaint, quotes the latter half of a sentence from my original article in the *British Journal of Dermatology*. Taking into consideration that some of the children were eventually weaned and the rash continued, the complete sentence does not appear to me to be unreasonable. It is as follows:

"It is difficult to conceive that in all of these cases the mother's milk was responsible for the occurrence of the attack although admittedly a child may become sensitized to a protein through its mother's milk."

He also mentions that I quoted the work of Sidlek and Knowles (*American Journal of Diseases of Children*, 1922). These authors state that they cured three cases out of twelve by appropriate restrictions of diet. My previous letter explains why such claims may be valueless—I am, etc.,

The Skin Department, The Royal Infirmary
Sheffield

December 17th.

INJECTION OF VARICOSE VEINS WITH CARBOLIC ACID

SIR,—With reference to Dr Dalton's interesting memorandum (December 8th, p. 1037) on the injection of varicose veins with carbolic acid, I think he is to be congratulated in his endeavour to find the perfect sclerosing agent in this treatment, but I feel doubtful about some of the advantages claimed for this medium.

His essential claim for carbolic acid is that it is non-toxic, in that, having destroyed the endothelial lining of the vein, it is at once locked up in the clot which forms immediately, and thus remains entirely local. Knowing the volatile habits of carbolic acid I find it hard to understand how an amount of the undiluted B.P. preparation up to half a drachm should remain entirely local, and it would seem desirable that more definite evidence should be shown before this claim can be established.

It is difficult to understand how such a small dose as two to four minims can produce true sclerosis in such a large area of varix, and indeed when, as Dr Dalton says, "sometimes a week after injection it is difficult to find the remnants of the vein." I venture to question if sclerosis such as is seen after injection of the usual agents ever occurred, for with a successful result, using these, the vein remains hard and vein definitely demarcated for months.

With regard to perivenous injection, I have become convinced that it should be avoided in every case, except possibly for the fine dilated venules which one is sometimes asked to treat on cosmetic grounds. If a varix cannot be entered with the needle, I cannot think any result of

value is obtained by depositing one or two drops of solution outside it. I know only too well that some veins are most difficult to enter, but I am sure that, given experience and the will to "try again," any vein of greater diameter than the needle can be made to yield eventually—I am, etc.,

London W 1 Dec. 10th

RONALD THORNTON.

SIMPLE PHLEBITIS AND EMBOLISM

Sir,—The correspondence on this subject in the *British Medical Journal* of December 1st and 15th makes no reference to the theoretical side of the question.

Rowntree and Shonova (*Journal of Experimental Medicine*, New York, 1927, vol 46, pp 7, 13, 19, 957, and 963) have recently carried out a very ingenious series of experiments at the Mayo Clinic with the intention of making direct observations on thrombus formation, and their findings suggest to me that in the case of traumatic phlebitis—whether by accident or design, as in the injection treatment of varicose veins—there occurs first of all a deposition of white thrombus in the damaged section of the vein, and as long as the circulation through the vein is kept up no red clot forms. This white clot is very strong and firmly anchored to the endothelium. As soon as the impediment to circulation is complete there is a more or less sudden deposition of red clot blocking the vein for some distance, spreading chiefly in the direction of the normal flow. This is an additional reason why patients undergoing the injection treatment of varicose veins should be kept walking about—namely, in order that they may get a firm (comparatively) white thrombus as the foundation of their occluding clot.

It is the experience of most of us that quinine injections, comparatively painless at the time, cause tenderness and swelling at the site of injection twelve to forty-eight hours later. I would suggest that this probably coincides with the complete blocking of the vein by white thrombus and the subsequent rapid deposition of red clot. In this aseptic thrombus there is no trypsin ferment, so that the clot does not become softened, and, therefore, is not easily detached.

I recently injected a woman who returned to me two days later in great alarm because, as she said quite correctly, she had phlebitis in the injected vein, and she recognized it from the symptoms being identical with a previous attack she had had several years ago. However, I gave her my usual advice to keep going about, and nothing untoward has occurred.

The above suggestions are an application of Rowntree and Shonova's findings to what I have observed clinically, and I should be interested to hear whether others agree with my theories or not. My experience of the injection of varicose veins has convinced me that in a traumatic phlebitis where sepsis can be definitely excluded as a causative or contributory agent the patient should be kept walking about. I entirely agree with the views of Dr. Crichton—I am, etc.,

Hove Sussex Dec 15th

STGEORGE B. DELISLE GRAY

"THE RIGHT TO PRACTISE"

Sir—Surely Dr. Macqueen (December 8th, p 1067) has got rather confused about the "rights" of this question. Only a medical degree or diploma gives the "right" to practise. There is nothing in the *Medical Register* which, in itself, gives any such "right." The *Medical Register* is a list to give the public an opportunity of distinguishing between "qualified" and "unqualified" practitioners. It also gives the qualified man on the register a legal right to sue in court, to sign death certificates, and by custom it has practically made all public appointments open only to those on the *Register*. If a man is taken off the *Register* he still possesses the legal right to practise provided his university or other qualifying body has not taken away his degree or diploma, and if he has these he can practise, but loses the "rights" under the medical registration—I am, etc.,

St Leonards-on-Sea Dec 8th

A. G. NEWELL M.D.

DEFINITION OF DRUNKENNESS

Sir,—Many years ago, when I was a young surgeon serving in a man-of-war with masts and yards, I was requested to examine a bluejacket charged with being drunk on duty. I reported to my captain that, though the man had undoubtedly been drinking, I hesitated to say that he was actually drunk. "In that case," said the captain, "if I order him to the masthead, would you consider it safe?" "Certainly not, Sir," I replied. "Then he is drunk," was the captain's decision, and appropriate punishment followed—I am, etc.,

London W 4 Dec 17th

V. G. THORPE,
Surgeon Rear Admiral

Medical Notes in Parliament (FROM OUR PARLIAMENTARY CORRESPONDENT)

THE House of Commons adjourned for the Christmas recess on December 20th, having on that day approved Supplementary Estimates for the relief of distress in the mining areas amounting to £155,000 for England and Wales, and £20,625 for Scotland. Discussing the administration of this relief in Scotland, Sir John Gilmour said that the addition of a milk diet would be of material benefit to school children in many cases, as recent official experiments had shown. It would be necessary that applications should come through existing channels, including the child welfare and maternity authorities. In the course of the debate on the estimates Mr. John protested against a statement previously made by the Minister of Education to the effect that local authorities should feed the children if medical certificates were issued that this was necessary, this meant, he suggested, that a child had to suffer from malnutrition before the medical officer of health would decide that it was in need of nourishment. Mr. Boothby suggested that Durham and South Wales should be administered independently of the health insurance fund, as otherwise the actuarial surplus would be irreparably damaged.

The House will resume its sittings on Tuesday, January 22nd, when consideration of the Local Government Bill in committee will proceed. Four of the thirteen days allotted under the guillotine resolution to this stage of the bill have already passed, and the House after the recess, will discuss the complex proposals relating to rating, valuation, Exchequer grants, and other financial provisions, and to certain general questions.

Local Government Bill

Consideration in committee of the House of Commons of the Local Government Bill was continued on December 18th, which was the third allotted day under the guillotine resolution.

Clause 13 enacts that as from the appointed day it should be the duty of every county council and county borough council and other local authority to recover from any person who has been maintained by them in any hospital, maternity home, or other residential institution in which accommodation is provided by the council other than a person who had become an inmate of an institution for the purpose of receiving treatment for infectious disease or from any person legally liable to maintain that person the whole of the expenses or such part as the council are satisfied they can pay.

Mr. Wren moved to omit the words "it shall be the duty of" which made it obligatory on the council to present the bill for the full amount. He said that the full amount as the clause stood appeared to include the whole cost of all the medical treatment, however expensive that might be. The North Middlesex Hospital, which was under the administration of the Edmonton Board of Guardians had just obtained the sanction of the Minister of Health for an expenditure of £6,000 on radium to bring its equipment up to date. It was better equipped than a good many voluntary hospitals in many respects. The practice here was to recover from the patients as much as the board of guardians thought it could recover up to the total limit of cost and in that connexion no question arose. The total cost last year was 49s. a patient per week. If the institution was handed over to the Middlesex County Council as it would be the bill would require the county council to make a charge of 49s. a week on every patient who used the institution although in the case of the board of guardians only about 15 per cent of the patients paid any contribution and in 85 per cent practically nothing was recovered. It would be a very serious change to make if instead of presenting a bill for 5s. 10s. 20s. or up to 49s. according to the means of the person in 15 per cent of the cases the local authority should be required to make the full charge of 49s. in all cases. If everyone who went into that hospital was told that he or she would receive a bill necessarily at the rate of 49s. a week with some prospect of the amount being reduced it would be he was informed by medical people concerned, a very serious deterrent to people going into that hospital at the earliest possible date. It would not be in accordance with the Minister of Health's intentions or desires to make this emphatic change and to insist that

instead of the bill being graduated according to the patient's means the full amount in each case would have to be presented.

Mr. PETERICK LAWRENCE seconded the amendment and drew the attention of the Minister to the case of the unmarried mother. He said that at present whether she was treated in a voluntary hospital, a special nursing home or an institution under a local authority, great care was taken to preserve the secrecy which might be necessary in these cases. Under the clause, however, if the woman herself was unable to produce any money, application would be made at once to members of her family—to her father or whoever might be responsible in law for her. The result of that would be that these women would not go into a home or institution to be treated. To day we recognized the full of not helping people to fight against infectious and venereal disease. Could it be suggested in regard to cancer, maternity and child welfare that the position was different?

Mr. CHAMBERLAIN in reply said that if the amendment were carried we should be exactly where we were now. Local authorities had this power at present. There was nothing in the bill which said, as Mr. Webb suggested, that the local authority must present a bill for the whole of the expense to a person receiving treatment. It was not contemplated that the local authority should do anything of the kind. They would do precisely what was done now in other cases. They would through their officers find out whether a person was able to pay anything and if so how much, and they would make those inquiries before sending in their bill. The object of the clause was to have one rule for both kinds of institutions. If there was not a provision of this sort the position would be that in the case of a destitute person treated under the Poor Law, it would be the duty of the local authority to recover the whole of the costs from him, or such part as he was able to pay, but in the case of a person who was not destitute and was able to pay there would be a discretion with the local authority. That was an anomaly which was being removed by this clause.

Mr. GREENWOOD supporting the amendment said that the Opposition did not so much regard the mere collection of the money as obnoxious but held that the new duty which was imposed on local authorities was bound to be a deterrent and would lead numbers of people who ought at an early stage seek institutional treatment to postpone it or not to go at all.

Dr. VZAVOR DAVIES said that Mr. Greenwood showed extreme lack of knowledge of the subject on which he had been speaking. Perhaps the hon. member would allow him (Dr. Davies) as an old medical officer of the Poor Law as a hospital official and as a general practitioner to let him know what really happened. In the majority of cases a person who was sick went first of all to his private doctor without any thought of what it was going to cost. The doctor examined him and if the case required treatment in an institution sent the man to the institution. In some of the large towns they would find occasionally that a patient instead of going to a doctor went to the out-patients department of a voluntary hospital and got some attention there without cost to himself. For Mr. Greenwood to say that the Government by the bill was trying to prevent people seeking medical assistance at the earliest possible moment was to say what was not true, and to put a false construction on the bill. The people of this country had known for years that they could always get medical assistance either from hospitals, Poor Law institutions or doctors, without any thought of the ultimate cost. Let them take the case of a general practitioner in an industrial district in the huge majority of cases. That doctor did not ask a patient

Where is your fee and then I will tell you what is the matter with you. (Opposition cries of Oh.) Labour members might speak from rumour or hearsay but their attitude was a distinct reflection and libel on a most honourable profession. He maintained without fear of contradiction that no man or woman in this country need delay for one moment in getting the most expert advice and the most expert treatment through fear of poverty or of the cost and there was nothing in the bill which would hinder them in the slightest degree. It was absolutely wrong for an hon. member on the Opposition front bench to make the statements which they had heard that afternoon but he asked the House and the people of the country to notice that this was the policy of the Labour party and that the destitute poor should be charged for medical attention but that the public health authorities need not make a charge. They were asking for this—to charge the destitute poor but not to allow the public authority to do so—and that was a scandal.

After considerable further discussion the amendment was rejected by 236 votes to 130. Miss BOWFIELD then moved an amendment to remove maternity homes from the operation of the clause and particularly from the operation of the uniform enforcement of the provision which had just been discussed. The work in connexion with maternal mortality, she said, was still in an experimental stage and anything which shook the present position was bound to act to the detriment of the service. For instance the psychological effect of making a provision so that the operation of the financial arrangements in regard to municipal maternity centres were on precisely the same lines as those of the Poor Law would be a deterrent so far as a great many women were concerned.

Sir KINGSLEY WOOD while agreeing as to the importance of making due provision for maternity and encouraging as many mothers as possible to enter maternity homes said that if Miss Bowfield thought that under this clause we were swapping horses and altering the present practice she was greatly mistaken. The provision which was being insisted in the clause generally was already the invariable practice so far as maternity homes both municipal and voluntary in the country were concerned. The clause so far from making any alteration really set out what was the universal practice of the voluntary maternity hospitals

and homes. Some sixty or seventy municipal maternity homes recovered appropriate contributions unless they were satisfied, having regard to the circumstances of the inmate that nothing could be paid. Therefore there was no ground for saying that there was any alteration in the practice or for anyone being frightened away from the maternity homes of the country by the application of the clause.

Replying in further debate, Mr. CHAMBERLAIN said that they were faced with the fact that there were not a sufficient number of maternity homes. They wanted more provided, but there would be still greater difficulty in getting local authorities to build more in future if they were faced with the prospect that when they had built them they were to be a heavy charge because they would not be able to recover expenses. The amendment was defeated by 250 votes to 145.

Mr. REKIE SMITH moved an amendment providing that the term infectious disease used in the clause should be stated to include tuberculosis and venereal disease. Sir KINGSLEY WOOD said that the Ministry's legal advisers had stated that both tuberculosis and venereal disease could be regarded as coming within the meaning of the clause relating to infectious diseases and that the amendment was therefore unnecessary. Dr. VZAVOR DAVIES said the Minister was now taking a rather important step. If they were to say that infectious diseases were to include in all cases tuberculosis and venereal disease how were they going to keep out infantile paralysis, encephalitis lethargica and influenza? The CHAIRMAN pointed out that the Minister had merely stated that these words as a matter of definition would include certain complaints. Sir HENRY SLESSER said that there was no definition at all of infectious disease in the bill. He wanted to know where the committee stood in the matter of definition? Was there no Act that defined infectious disease? Sir THOMAS INSKIP said that the committee never wanted the legal arguments if a little common sense would solve the problem. The words 'infectious disease' were words which meant that a disease was infectious and which so long as people were at large might result in injury to other persons. The result was that people who suffered from what were in fact infectious diseases were required in the public interest to go into an institution for treatment. It was better to leave the question of what was an infectious disease to be solved by proper evidence of fact if ever such a question arose. He had very little doubt that those questions of fact would be solved by the common sense of the doctor and authorities without any necessity to resort to a court of law.

Dr. FREEMANTLE said that he dissented from the reading which the Attorney General had just given. He could foresee his colleagues of the medical profession having to administer the Measure and they must know what cases they were dealing with, and what cases they were not dealing with under it. In the ordinary terminology of public health the phrase 'infectious disease' had a definite meaning. It was defined by an Order of the Ministry of Health interpreting certain Acts of Parliament in relation to infectious diseases. There was a specific catalogue of the diseases which were included in this definition. It was easy to administer a Measure of this kind on those lines, but if his hon. and learned friend had the good fortune to belong to the medical instead of the legal profession and, as a medical officer had to try to work the administration of Acts relating to infectious diseases on the lines which he himself had suggested, he would find it an impossible task. They must have it laid down what diseases were to be regarded as infectious diseases. For practical purposes venereal disease was not called an infectious disease and certainly nobody had ever suggested that cancer was an infectious disease. He (Dr. Freemantle) suggested that the Minister of Health might reconsider this question in order to insert in the definition clause something regarding the words 'infectious disease' being definitely associated with the term as generally interpreted in other Acts. Sir KINGSLEY WOOD after further discussion said it was not a question of his own opinion but of fact as to whether a disease was infectious or not. If his own opinion was of any value he should say that certainly tuberculosis would be included but that was only his opinion. The advice given to the Department was that the amendment was unnecessary. The committee rejected the amendment by 258 votes to 145.

Under the guillotine resolution the clause was agreed to by 270 votes to 147. Clauses 18 to 28 were afterwards agreed to under the guillotine without discussion. Clauses 18 to 24 dealt with registration. Clause 26 with roads and town planning and Clause 28 with the transfer of classified roads in urban districts to the county council. The committee then adjourned until the following day.

On December 19th the House of Commons was again in committee on the Local Government Bill. During prolonged discussion on the clauses dealing with control of highways and the alteration of boundaries of authorities brief allusion was made to the effect the bill might have on town planning schemes. Several clauses of medical interest subsequently came under the guillotine. Clause 45 regulating the relations between county councils and county district councils in respect of public health functions was approved without amendment. Clause 46 provided that county councils, after conferring with district councils shall formulate schemes for securing the appointment of whole-time medical officers of health. The clause provided that every county council making such arrangements should send a copy of the scheme to the Minister and to the councils of the districts affected. Mr. CHAMBERLAIN now moved to provide that every such council should be at liberty to make representations on the scheme to the Minister. The amendment was carried and the clause as amended was added to the bill. Clause 47 authorizing regulations to prescribe the qualifications of medical officers and

health visitors appointed under the Maternity and Child Welfare Act the Public Health (Tuberculosis) Act or under regulations for the treatment of venereal disease, was added to the bill. Clause 48 gave the Minister power, when satisfied that his action would conduce to more efficient administration to transfer any services under the Maternity and Child Welfare Act to the council which was the local education authority. Mr CHAMBERLAIN moved to substitute the word 'effective' for the word 'efficient'. This amendment also stood in the name of Dr VERNON DAVIES. The clause was carried so amended. Clause 49 giving the Minister power to declare that the Notification of Births Act should apply in an area whose council had not adopted it was carried. Unamended. Clause 50 sets out the conditions under which a district council may apply to be made local supervising authority under the Midwives Acts in place of the county council. Mr CHAMBERLAIN moved an amendment to provide that the Minister should consult with the county council before granting such an application. The clause thus amended was added to the bill by 258 to 118 votes. Clause 51 dealing with the provision of accommodation for infectious diseases and with the formulation by county councils in consultation with district councils of schemes for that purpose was carried by 251 to 119. Clause 52 authorising the Minister to empower the transfer of functions from the London County Council to metropolitan borough councils was also added to the bill as was Clause 53.

On January 22nd when the House again goes into committee on the Local Government Bill the clauses relating to rating and valuation will be considered.

Preservation of Infant Life Bill

In the House of Lords on December 18th the Preservation of Infant Life Bill was read a third time. Following the third reading Lord DARLING moved three amendments to Clause 1. The clause originally read

Any person who with intent to destroy the life of a child capable of being born alive by any wilful act causes a child to die before it has an existence independent of its mother shall be guilty of felony to wit child destruction and shall be liable on conviction thereon to imprisonment to penal servitude for life provided that no person shall be convicted of an offence under this section if it is proved that the act which caused the death of the child was done in good faith for the purpose only of preserving the life of the mother.

Lord DARLING said that on the committee stage it was pointed out that there were occasions in which it was necessary at the confinement of a woman in order to save her life that the child about to come into the world should be destroyed. He feared that it must be very rare that that should be done in good faith but it was stated that it might arise and that a third person might be indicted though having acted in good faith. That was provided by the proviso in the clause beginning with the words provided that no person shall be convicted and so on but it was then pointed out that it might be said that the onus was upon the person—who would be a third person—who had destroyed the child to prove that he acted in good faith for the purpose of saving the life of the mother. He would therefore move three amendments which would place the onus on the prosecution so that it would be necessary for the prosecution from the start to prove—or else there would be no case to go to a jury—that the person who was accused of destroying the child had not done so dishonestly and in good faith. His amendments would make the proviso read

Provided that no persons shall be guilty of an offence under this section unless it is proved that the act which caused the death of the child was not done in good faith for the purpose only of preserving the life of the mother.

Lord PARMEER expressed his satisfaction with the amendments which made it quite clear that the onus of proof was on the prosecution. The LORD CHANCELLOR said that Lord DARLING had produced the amendments partly after seeing him to make it quite clear that the burden of proof had been shifted. He thought that the amendments did so.

The amendments were agreed to and the bill was passed, and sent to the House of Commons.

Medical Directors of the Services: Tenure of Office

Sir L. WORTHINGTON EVANS stated in reply to Sir H. CAYNOR on December 18th that the appointment of Director General of the Army Medical Services was for four years but an extension was permissible. As the present Director General had held office for two and a half years only no question of extension had arisen in it of Medical Director General of the Navy was normally for three years but this period might be extended if the Board of Admiralty thought it desirable. The present Medical Director General was appointed on July 1st 1927 and the question of an extension therefore did not yet arise. Sir S. ROBERTS stated that the tenure of the appointment of the Director of Medical Services in the Royal Air Force dated from November, 1921. An extension had recently been granted until November 1930. The question of any further extension would be considered on its merits when necessary in the light of the circumstances then existing.

Merchandise Marine Health Committee

On December 18th Sir P. CUSSETT LISTER told Lieut. Commander Kenworthy that the personnel of the Joint Standing Committee set up by the Ministry of Health and the Board of Trade on matters affecting the health of the mercantile marine was made up of the Board of Trade Sir Charles Hipwood (chairman), Mr C. E. Baker, Mr A. S. Hoskin and Mr C. J. Oves (clinical secretary) representing the Ministry of Health Sir George Buchanan, Dr H. A. Macerwan, Mr M. Heseltine, Mr R. H. Crooke and Mr M. T. Morgan (medical secretary).

Milk Supplies to Expectant Mothers.—Sir H. ASLEY WOOD on December 18th told Mr. March that no request had been made to authorities to cut down the supplies of milk to expectant mothers and children who were attending the maternity and child welfare centres but in the case of some local authorities suggestions as to procedure were made last March with a view to enabling them to keep their expenditure on milk during the present financial year within the amounts which the Minister of Health was able to approve for grant. The Minister had received communications from forty-eight authorities requesting that these amounts should be increased and, in reply, he had explained that the reduction in grant—which was purely temporary—had to be made in order to keep the grants paid by the department for the health services within the amount voted by Parliament.

Post neonatal Pneumonia.—Mr. BRINT asked Mr. Chamberlain on December 13th whether he would direct the Registrar General to make a note in his next annual report in regard to the deaths from post neonatal pneumonia since 1922 which were brought to the notice of the Andrewes and Rolleston Committees though not so certified at the time the deaths occurred. Mr. CHAMBERLAIN said the classification of deaths in the Registrar General's statistics was in all cases based on the cause as certified by the medical practitioner or the coroner. A departure from this practice would not be justified.

Artificial Light Treatment Centres.—Sir H. ASLEY WOOD told Sir Robert Thomas on December 19th that 237 centres for administering artificial light treatment had been approved by the Ministry of Health or by the Board of Education. Establishment of such centres was primarily a matter for the local authorities and steady progress was being made with it. Sir ROBERT THOMAS recalled a statement that 53 per cent of the children of the nation suffered from rickets or its effects. Sir H. ASLEY WOOD said this figure was given in the annual report of the chief medical officer of the Ministry of Health for 1926. It related to a portion of a comparatively small sample of the 1,000 children who were specially examined and included all who showed the slightest signs of rickets.

First-aid Equipment on Road Vehicles.—On December 18th Mr. RANDELL asked leave to bring in a bill to regulate the first aid equipment of public passenger service vehicles on roads. He said that the object was to ensure that on all public passenger vehicles such as motor omnibuses and charabancs there should be carried a first aid outfit and that there should be someone on the vehicle competent to use it. The bill would not apply to railway carriages, trams, or trolley vehicles. The regulation as to the outfit and by whom it should be carried would be left to the Minister of Transport. Leave was given to introduce the bill and it was read for the first time. Dr. Drummond Shiels was one of the backers of the bill.

Maternity and Child Welfare Grants.—Mr. CHAMBERLAIN stated that the grants paid for maternity and child welfare out of the Ministry of Health Vote in 1927-28 were approximately £1,040,000 which included about £16,000 for training of midwives and health visitors.

Deaths from Gaseous Poisoning.—In a reply on December 19th to Mr. BOWERMAN, Mr. HENDER WILLIAMS said that in 1913 there were registered in England and Wales 89 accidental deaths from gaseous poisoning, 40 being from coal gas and 160 suicides by gas, 150 being by coal gas. In 1927 the comparable figures were: Accidental deaths from gas 195 (148 from coal gas), suicides by gas 998 (994 from coal gas). Mr. BOWERMAN asserted that since the war the percentage of carbon monoxide in coal gas had been raised from 7 per cent to 15 or 20 per cent. He asked whether steps could be taken to ensure thermal efficiency in some manner less dangerous to the public. Mr. WILLIAMS replied that the increase in the content of carbon monoxide was due to the increased use of water gas a development which had many advantages. The possibility of safeguards against carbon monoxide had been considered by various committees and by the gas industry but the problem was far from easy.

Veneral Disease.—Answering Mr. Ellis Davies on December 19th Sir H. ASLEY WOOD said that in England and Wales during 1927 cases of venereal disease dealt with for the first time at treatment centres equalled 21.5 per 10,000 of the population. In the county of Carnarvon the proportion was 6.5 per 10,000. These figures included large numbers who had been infected some time before they attended at a treatment centre.

Mortality of Disabled Ex-service Men.—Mr. TAYLOR told Lord Soudon on December 13th that there was no record of the mortality of ex-service men at large as distinct from the general population. The death rate for the whole body of disabled officers and men was estimated for the current year at about 15 per 1,000. This was probably higher than the death rate among the general male population of similar age as would be expected.

Votes in Brief

Sir Laming Worthington Evans reports that the numbers of men discharged from the army because they were suffering from tuberculous disease were in 1924 174 in 1925 227 in 1926 223, in 1927 201. The last two figures include men discharged from the Reserve or Territorial Army for the same reason. The number of cases accepted as attributable to military service and awarded pensions was in 1924 43 in 1925 26, in 1926 67, in 1927 53.

Sir H. ASLEY WOOD stated on December 19th that on December 1st more than 21,000 patients were receiving residential treatment for tuberculosis from local authorities in England and Wales. On that date 2,541 persons had been awaiting such treatment for more than ten days.

Dr. Elliot states that so far as national health insurance is concerned it has never been the practice to publish Scottish

decisions, but that the whole question of appeal procedure under the Health Insurance and the Widows' Pensions Acts will shortly come up for review.

The Home Secretary is advised that he has no power to give retrospective application to the regulations for granting compensation to men disabled by silicosis.

There is not sufficient evidence to warrant a general conclusion about the effect on health of work in basement rooms by clerks and warehouse staffs, and Mr Chamberlain cannot promise a special investigation at present but he remarks that local authorities have power to deal with insanitary conditions.

Obituary

JOSEPH PRIESTLEY, M D, D P H,

Late Medical Officer of Health to the Borough of Lambeth.

THE public health world in particular and his many friends heard with deep regret of the death of Dr Joseph Priestley on December 15th.

Joseph Priestley, who was a descendant of the discoverer of oxygen, was born in 1859, and received his medical education at Edinburgh, where he graduated M B, C M, in 1883, obtaining the diploma M R C S Eng in the same year. He proceeded M D with honours in 1886, and four years later became D P H Camb. He devoted himself at first to clinical practice, and held the posts of house surgeon to the Royal Infirmary at Manchester, clinical assistant to the Brompton Great Ormond Street, and Royal Westminster Ophthalmic Hospitals, and intern at the Rotunda Hospital, Dublin. After a period of private practice at Twickenham he went to Cambridge as medical officer of health, and subsequently became medical officer and public analyst to the borough of Leicester. There he made a name for himself by courageous and effective reforms, and so reached Lambeth in 1895 with a reputation already high.

Here, for thirty-two years, his exceptional energy and ability found suitable outlets in the control, or development, of many great health measures. He was prominent in stamping out a serious small-pox epidemic, which invaded the metropolis in 1902, in so far as Lambeth was concerned. He took an active part in closing many dilapidated and worn-out properties, and attending, as an expert witness, various public inquiries with regard to condemned areas. He promoted the establishing of dispensaries for tuberculosis, and conducted investigations with regard to food poisoning. He brought about the provision of many welfare centres throughout the borough, and also a maternity home and a milk depot. When he retired last year he was presented by his medical colleagues and friends in Lambeth with a silver salver as a token of their warm regard for him and high estimation of his services.

Naturally profoundly minded, he had a wide range of interests. He was a foreign member of the Society d'Hygiene, and a Fellow and lecturer of the Royal Sanitary Institute. He had also held the appointments of assistant examiner in hygiene, South Kensington, lecturer on hygiene to the Jenner Institute, honorary secretary to the Society of Medical Officers of Health, and lecturer to the St John Ambulance Association. His work lives on in the memory of his many admirers, and Lambeth is his best testimonial.

THE LATE DR J McASKILL HENDERSON

DR H E MAGEE (Aberdeen) writes.

THE untimely death of Dr John McAskill Henderson has spread a gloom over a wide circle both in this country and in Kenya and has cut short a life full of great promise. As a student in the University of Edinburgh he had a distinguished career graduating in arts, science and medicine. He was prominent in the social life of the University and was for varying periods president of the SRC, the Union and of the Celtic Society. During the war he was employed as a chemist in a munition factory, having been rejected for military service. After graduating in 1922 he engaged for some time in general practice in Glasgow and then decided to take up research as a career. He came to the Rowett Institute at the end of 1923, and worked on the effects of ultra violet light on

metabolism, and on problems connected with lactation. He had just begun to investigate the metabolism of iodine when he went out to Kenya with other medical and agricultural graduates from Aberdeen, in charge of the medical team to conduct an inquiry into nutritional problems in that colony. His work there was characterized by the same enthusiasm, thoroughness, and sound judgement as had been the case in Aberdeen, and it has thrown a new light on many problems concerning the health of the native. He had just concluded his experiments, and was about to leave for Aberdeen to attend to the publication of his results, when he contracted the disease which proved fatal. While his results remain as a contribution to medical science, the ideas derived from them by a foreseeing and constructive mind he buried with him. Henderson had a remarkable flow of English at his command, both in its written and spoken form. He was always precise and lucid. His published articles are a delight to read, and his ability as a speaker will be long remembered. He was a man of extremely wide interests and of great broadness of mind. He was well versed in literature, music, and art, and was himself no mean exponent with the brush and pencil. His ready wit, his great fund of anecdotes and amiable personality will be missed in the many social gatherings he attended. Great sympathy is felt for his young widow and his relatives.

Dr FRANCIS W T HARE died at Beckenham on December 9th at the age of 72. He was born in Dublin, and from Lettes College, Edinburgh, went to study medicine in London, first at St Thomas's Hospital and afterwards at St Mary's. He obtained the M R C S Eng diploma in 1879, and the M B degree of the University of Durham in 1884, proceeding M D in 1891. After some years in Australia, where he acted as medical superintendent of Charters Towers Hospital, resident medical officer of the Brisbane General Hospital, and inspector of civil hospitals in Queensland, Dr Hare returned to England in 1904 and became medical superintendent of the Norwood Sanatorium, a post he held for over twenty years. The fruits of his wide experience in the care of patients suffering from alcoholism and drug addiction were set out in a book published in 1912 under the title *Alcoholism Its Clinical Aspects and Treatment*. An earlier work from his pen, the *Food Factor in Disease*, was published in two volumes in 1905.

We regret to announce the death of Dr DONALD CLARK, at Sydney, on October 12th. Dr Clark, who received his medical education at Glasgow, and graduated M B Ch B in 1908, settled in Salonika after the war, where he was consulting medical officer to the British consul. He devoted himself unsparingly to the medical supervision of the large number of refugees who went to this town, particularly after the Smyrna disaster, and was appointed director of the Harman Koni Hospital, which was opened for them. The incessant strain of the work and chronic malarial disease took a heavy toll of his strength, and he never regained full health, though he was able to do a certain amount of medical work when he left Greece and went to live in Sydney two years ago.

The Services

THE Royal Naval Volunteer Reserve Officers' Decoration has been awarded to Surgeon Commander L S Ashcroft.

ROYAL ARMY MEDICAL COLLEGE PRIZES

THE following prizes have been awarded to the officers of the last Junior Officers Class at the Royal Army Medical College.

Herbert Prize (for highest aggregate) Lieutenant F S S Lucas I M S (St Thomas). First Montefiore Prize in Military Surgery Lieutenant E S S Lucas I M S. Second Montefiore Prize in Military Surgery Lieutenant C L Grieve R A M C (Glasgow University). Ronald Martin Prize in Tropical Medicine Lieutenant M R Sinclair I M S (Cambridge and St Bartholomew's). Parkes Memorial Prize in Hygiene Lieutenant G L Grieve R A M C and Lieutenant H W Farrell I B S (University College Dublin) (equal). Talbot Memorial Prize in Pathology Lieutenant A T H Marsden R A M C (University of Durham). Farrer Memorial Prize in Pathology Lieutenant V E M Lee I M S (R C S Ireland). Marshall Webb Prize (Medical Administration) Lieutenant A T H Marsden R A M C.

Universities and Colleges

UNIVERSITY OF OXFORD

A Wan Memorial Medical Scholarship at University College has been awarded to B B Hlokey

UNIVERSITY OF CAMBRIDGE

At a congregation held on December 19th the following medical degrees were conferred

M B. D. Cunn—M T. Clegg
B. Cunn—L R. Jones

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Six Munterian lectures on the anatomy and evolution of the human brain will be delivered by Sir Arthur Keith F.R.S. in the theatre of the Royal College of Surgeons of England, Lincoln's Inn Fields W.C. on Mondays Wednesdays and Fridays at 5 p.m. commencing on January 14th 1929. The first lecture will consist of a sketch of the present knowledge regarding evolution of the brain in higher primates, the second will deal with the growth of the human brain and a discussion as to the significance of the mass, the third will define the present state of knowledge concerning the cortical areas of the human brain the fourth will be devoted to recent studies of the brains of men of outstanding ability and a survey of the general results obtained by such studies the fifth will comprise a study of the brains of the microcephalic idiots and what can be learned therefrom and the last lecture on January 25th 1929 will discuss endocranial casts from fossil skulls and the light they throw on the evolution of the brain of man

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

Medical News.

ACTIVE steps are being taken by the Asthma Research Council, with the approval of the Ministry of Health, to organize research into asthma and the diseases commonly associated with it, including hay fever, eczema, and urticaria. It is estimated that there are over 200,000 sufferers from asthma in Great Britain, in at least 50 per cent of cases the disease begins in childhood. The "Halley Stewart" Trust, which was founded in December, 1924, to advance religion and education and to promote charitable objects, has made a grant of £2,500 to the Asthma Research Council for the establishment of special asthma clinics at Guy's Hospital and Great Ormond Street Hospital for Sick Children. The Lord Mayor of London will preside at a meeting at the Mansion House on January 15th, at 3 p.m., to inaugurate a national fund to provide and endow asthma research clinics at other London hospitals and in many of the large provincial towns, including Manchester, Liverpool, Glasgow, Birmingham, Bristol, Leeds, and Belfast. The meeting will be open to asthma sufferers and their relatives and to others interested in the subject, those desiring to attend should communicate with the Secretary, Asthma Research Council, London Clinic, Rauceigh Road, S.W.1

THE Central Midwives Board for England and Wales met on December 6th, with Sir Francis Champneys in the chair. A special session was followed by the ordinary monthly meeting. Consideration was given to the Local Government Bill, 1928, as it affects the supervision of midwives. The dates for meetings for 1929 were arranged for the first Thursday in each month, with the exception July 18th, no meetings will be held in August or September. The secretary reported that there were 14 per cent of failures at the last examination.

THE National Council for Mental Hygiene has arranged a series of eight lectures, to be delivered on successive Wednesday days, at 5 p.m., at the rooms of the Medical Society of London, 11, Chandos Street, Cavendish Square, W.1. The first lecture, entitled "Dangerous Ages—Childhood," will be given by Dr J A Hadfield, on January 23rd, 1929. Tickets (price 1s 6d each, or 10s for the course) may be obtained from the Secretary, National Council for Mental Hygiene, 78, Chandos House, Palmer Street, S.W.1

THE Mental After Care Association, which was founded in 1879 and is the only charity of its kind in the United Kingdom, is appealing for funds to carry on the work of caring for mental convalescents. Last year the association dealt with about 2,000 cases, and its work is expanding steadily, as an increasing number of persons are being referred to it by the committees and medical superintendents of mental hospitals. Local associations are being set up in many parts of the country. The association arranges convalescent accommodation where required, provides material assistance, secures employment, reports upon cases, and in other ways assists in the rehabilitation of persons discharged from mental hospitals. Information may be obtained from the Secretary, Miss L D Vickers, Church House, Westminster.

THE Home Secretary announces that in pursuance of the International Opium Convention of 1925 he has made new regulations under the Dangerous Drugs Acts. Consolidated regulations, replacing those now in force and including the drugs brought in by the Convention, will come into force on January 1st, 1929. On and after that date, in addition to drugs which are already controlled, coca leaves, Indian hemp (including the resins, extracts, and tinctures), and preparations containing less than 0.1 per cent. of diacetylmorphine (heroin), can be dealt in only by persons licensed or authorized by the Secretary of State.

As a result of the four performances of Dr John Ferguson's comedy, *Healing Waters*, given in the Athenaeum Theatre, Glasgow, in November, a sum of £250, the amount realized after paying expenses, has been handed over by the Albany Players to the Glasgow Branch of the Royal Medical Benevolent Fund Guild. The play was a marked success, the theatre being crowded throughout the production. Members of the medical profession constituted a large part of the audience.

A POST GRADUATE course to be held in Vienna from February 18th to March 2nd will deal with diseases of the digestive organs and of the metabolism. At the conclusion of the course six days will be devoted to special clinical instruction. Other courses to be held next year include surgery, orthopedics, ante-natal treatment, gynecology, and urology, in the first fortnight of June, the latest developments in medicine, in September and October and a course on the internal secretions from November 25th to December 8th. From May 21st to June 29th there will

be a course in English of systematic training in neurology and psychiatry at Professor Wagner von Jauregg's neuro-psychiatric clinic and at the Neurological Institute of Professor Marburg, under the auspices of the American Medical Association of Vienna. Further information may be obtained from Dr E Spiegel, Falkstrasse 3, Vienna I.

THE International Labour Office has published five more leaflets, Nos 129 to 133, dealing with noises, the timber industry, explosives, metal grinding and polishing, and radium and radio active substances. They may be obtained from the director of the London office of this organization, 12, Victoria Street, S W 1.

THE first International Hospital Congress will be held at Atlantic City, U S A, from June 12th to 19th 1929, and will be attended by hospital doctors, nurses, superintendents, architects, and engineers. The subscription is five dollars. Further information can be obtained from Dr René Sand, 2, Avenue Velasquez, Paris.

THE nineteenth congress of the Italian Phreniatric Society will be held at Ferrara in 1929, when the following subjects will be discussed: temperament and character in psychiatry, introduced by Montesano and Kolyinsky, and fresh problems in psychiatry, with special reference to mental hygiene, introduced by Beranini, Modona, and Tumati.

BERLIN had a slight excess of deaths over births in 1926, and the excess was greater in 1927, when the total number of births was 42,696 and of deaths 48,742. Owing, however, to the excess of immigrants over emigrants, who amounted to 81,132 last year, the city continues to grow.

THE centenary of the foundation of the Psychiatric Institute of Palermo, of which Professor Giovanni Dotto has been the director for the last thirty years, has recently been celebrated.

PROFESSOR ADOLF WINDAUS of Göttingen, the discoverer of ergosterin, has been awarded the 1928 Nobel prize for chemistry.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the Journal should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are *MUSICAL 9361, 9362, 9363, and 9364* (internal exchange four lines).

QUERIES AND ANSWERS

TREATMENT OF MEMBRANOUS COLITIS

"A COUNTRY DOCTOR" asks for suggestions for the treatment of a long standing case of membranous colitis in a woman aged 33. Repeated doses of castor oil by mouth and olive oil and plain water enemata give relief but only temporarily. All forms of dieting suggested have been tried, including one of milk and bananae only. The attacks usually last four to five weeks they are followed by eight to ten days of good health and recurrence ensues without apparent cause. The patient is otherwise fit and not of a neurotic type.

INCOME TAX

Obsolescence Allowance

J C" refers to a reply to an inquiry from him which appeared in our issue of November 10th (p 378) and enclose the Inspector's reply to his further communications.

The Inspector has referred the point to his headquarters and the Inland Revenue Department evidently intend to stand

firm on the strict verbal construction of the rule—that is, in the case of an obsolescence claim regard can be had only to "the cost of the car replaced," even when that represented a temporary falling off in the standard of car equipment of the practice. The result in such circumstances is inequitable, except that the depreciation allowance which can be simultaneously claimed will restore the equity over a period of years. We cannot advise "J C" to carry the matter further.

LETTERS, NOTES, ETC

THE CIVIL POPULATION AND CHEMICAL WARFARE

DR T R HUMPHREYS (Wokingham) has prepared for the use of the St John Ambulance Association a pamphlet on the *Protection of the Civil Population in Chemical Warfare*, which has received the approval of the Chemical Warfare Research Department at the War Office. The pamphlet, which is of a practical nature, discusses the protection rendered by gas tight rooms, and the first aid measures for gassed or wounded civilians. Interesting information is given about the way in which ground, houses, food, and clothing may be contaminated by poison gas and details of decontamination processes are supplied. Although it is not easy to anticipate all the various difficult conditions which would result from gas attacks on large towns yet this pamphlet can be recommended to the attention of medical practitioners who would in such circumstances find themselves faced by exacting duties and puzzling situations. The pamphlet (price 3d) may be obtained from the St John Ambulance Association, St John's Gate, Clerkenwell, E C 1.

SODIUM NUCLEINATE AND PNEUMONIA

DR S A MONTGOMERY (Cleethorpes) writes: Having seen the virtues of sodium nucleinate praised from time to time by contributors to the *British Medical Journal* I tried it in one of my own patients in the hope that it might shorten a lobar pneumonia and possibly prevent an empyema from developing. The first injection of 3/4 grain was given about twenty four hours from the onset, and then similar amounts at four hour intervals till 3 grains in all had been injected. Morphine and strychnine 1/60 grain were also given for the first three or four nights to ensure rest and sleep. Far from there being an early crisis, even at the end of eleven days there was no sign of the temperature falling to normal. The patient's condition began rapidly to deteriorate with marked falling off of appetite, a spasmodic coughing, and retching, yet no purulent material appeared in the sputum. The presence of pus in the pleural cavity was not confirmed by needling various interspaces with a long serum needle. As the patient's condition was growing steadily worse, a rib was resected, on opening into the pleural cavity several adhesions were found, but still no pus, so it was decided to insert a drain and leave it. After another three days purulent material poured out through the tube the temperature rapidly fell to normal and the condition quickly improved. Dr Muir of Hull who saw the patient, agreed that it was a case of interlobar empyema. The patient was a strong athletic man, aged 40, and in perfect health prior to the onset of pneumonia.

THE CAMPAIGN AGAINST TUBERCULOSIS

DR A W CRAWFORD (Bolton) writes: In your report on October 20th (p 714) of the Conference of the National Association for the Prevention of Tuberculosis I noticed that the American Indian suffered from tuberculosis in epidemic form but there was no word about the origin or how the bacillus was propagated. This was surely an opportunity lost. We have not yet found any means by which the disease once established, can be eradicated, so that all our methods of treatment are simply tentative. I suggest that the following points should receive some attention: Do human beings pass on the disease from one to another? Do the lower animals do so? Do human beings transmit the disease to the lower animals? Do the lower animals return it to the human? To settle these points in my opinion, would be a step towards the eradication of the problem. Our present methods are like plucking the leaves off a tree and allowing the tree to grow.

1929 MOTOR LICENCES

To assist motorists the Automobile Association has issued a book, *Your Motor Tax at a Glance*, which shows the amounts due for licences, according to horse-power, either for the year or shorter periods. Information is also given concerning rebates obtainable in respect of old cars, refunds for surrendered licences, and the procedure for renewing licences. It is well to remember that the authorities are granting fourteen days' grace for the renewal of licences, and that vehicles used during this period of grace become liable to taxation. Copies of the booklet may be obtained upon application by postcard to the Secretary, the Automobile Association Fanny House, New Coventry Street, W 1, or to any of the A.A. area offices.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals, will be found at pages 34, 36, 37, 39 and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 250.

INDEX TO THE EPITOME FOR VOLUME II, 1928.

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Renal and Kidney, Cancer and Carcinoma, Epithelioma Malignant Disease, New Growth, Sarcoma etc., Child and Infant, Bronchocoele, Goitre, and Thyroid, Diabetes, Glycosuria, and Sugar, Eye Ophthalmia, and Vision etc

The Figures in this Index refer to the Number of the Paragraph, NOT the Page

A.

Abdominal adhesions 388
Abdominal operations, spinal anaesthesia in 227
Abdominal reflexes in epidemic encephalitis 42
ABELLA, R. Serological differentiation of
 Brucella abortus and *Brucella melitensis* 467
Abscesses, cold, treatment of 76
Acetabular cavity involved by fracture, 160
Achalasia, pyloric, and gastric ulcer 407
Acidosis in methyl salicylate poisoning 184
Actinomyces of the central nervous system 23
ADAMSON G. L. Pre-operative treatment of
 Graves's disease 494
Addison's disease in the negro 449
Adeno-carcinoma, primary. Of the duodenum
 189—Of the epididymis, 340
Adhesions, amniotic fluid as a preventive of 430
ADLERBERG D. Pituitary treatment of diabetes
 insipidus 457
Adnexa, tumour of operative treatment of 65
Adnexal diseases inflammatory treatment of
 506
Adrenaline asthma and blood pressure 50
Adrenaline resuscitation after intracardiac in-
 jections of 369
Agranulocytosis 117
ADOLPH C. Etiology of yellow fever 112
ADAMS B. Blood changes during malarial
 paroxysms 465
AITEEN A. Blair. Neuro-carcinoma 498
 "Akiyami." See *Leptospira autumnalis*
ALBUO G. X ray diagnosis of early pregnancy
 451
Aluminaric orthostatic and tuberculosis 325
Alcoholic cirrhosis. See Cirrhosis
Alcoholism, clinical aspects of, 259
Alcoholism and pellagra 514
ALDRICH, G. A. Acidosis in methyl salicylate
 poisoning 184
ALEXANDERSCO-DERCI, C. Venous blood pressure
 in hyperplasia 239
ALMERI, E. Multiple tumours of the female
 genitalia, 151
Alkalosis in peptic ulcer treatment of 243
ALLEY A. W. Protein therapy in peripheral
 vascular diseases 520
ALLEN I. M. Sensory phenomena following
 removal of a tumour of the sensory cortex, 460
ALLEN N. M. Post-operative jejunal ulcer 339
Allopecia premature 512
ALSTON J. Therapeutic action of magnesium
 sulphate 455
Amaraurosis temporary complicating pertussis
Amblyopia, post partum haemorrhagio, treated
 by transfusion 453
Ammonium ortho-todxybenzoate in arthritis
 233
Amniotic fluid as a preventive of adhesions 430
Anaemia familial with splenomegaly in
 infancy 493
Anaemia grave, in chronic nephritis, 424
Anaemia infection of Edinmann, 327
Anaemia, pernicious, liver fractions in, 531
Anaemia pernicious liver treatment of 38
 39 70 291, 500, 531
Anaemia, pernicious, of pregnancy 56
Anemias of childhood, liver administration in
 291
Anaesthesia carbon dioxide 228
Anaesthesia epidural in obstetrics, 376
Anaesthesia, open ether in India 392
Anaesthesia in gynaecological and obstetrical
 operations, 606
Anaesthesia, the heart during 524
Anaesthesia local. In the reduction of fractures,
 394—For abdominal Caesarean section 493
EPI 2

Anaesthesia, nitrous oxide-oxygen, mortality in
 84
Anaesthesia scopolamine in obstetrics 108
Anaesthesia, spinal, 86 393—In abdominal opera-
 tions 227
Anaesthesia surgical blood changes during 523
Anaesthetics choice of, 85
Analgesia stovaine 229
Anaphylactic asthma relieved by bleeding, 225
ANDERSEN M. Siggaard Insulin as a fattening
 agent, 458
ANDREZ O. Angioma and trauma, 517
ANDRES A. The effect of glucose upon the
 esterification of cholesterol 422
Anencephalic foetus. See Foetus
Angina pectoris treated by deep x rays, 105
Angina Vincent's 73 362—Carriers in 286
Angioma of kidney, 159
Angioma and trauma 517
Angor ocularis, 517
Ankle-clonus the nature of 148
Anthrax the mechanism of infection in 93
Anthrax bacilli effect of on tissue cultures 510
Anti anthrax serum the precipitating and pro-
 tective powers of 436
Antidiphtherial and antityphoid inoculation
 combined 447
Antidiphtherial serums efficacy of 234
Antigen treatment. Of external tuberculosis 164
 —Of Hodgkin's disease 477
Antipneumococcal serum in lobar pneumonia 104
Antirachitis prophylaxis, the practicability of
 561
Antitoxin in tetanus. See Tetanus
Antityphoid and antidiphtherial inoculation
 combined, 447
Antityphoid inoculation, 470
Antivirus Besredka's 436
Antral suppuration treated by suction 252
Aortitis, syphilitic, specific treatment of 195
Appendicitis, acute 515
Appendicitis, acute, and epididymitis differen-
 tial diagnosis of 143
Appendicitis in measles 192
Appendicitis in middle age 7
Appendicitis, pregnancy complicated by 21
Appendicectomy indications for 246
Arachnoidectomy, 56
AREOS J. M. M. Tuberculous synovitis, 364
ARMAND-DELLIE, P. Administration of ergo-
 sterol in rickets, 501
AROLD L. Passage of living bacteria through
 the intestine, 255
ARNOVLJEVIC, V. Interpretation of the ven-
 tricular electro-cardiogram 450
Aromatized blennorrh. See Blennorrh.
ARMILAGA F. O. Angina pectoris treated by
 deep x rays, 105
Arsenic in chorea 368
Arsenic in lamblia infestation 314
Arterial resection in obliterating arteritis 141
Arterio-sclerosis peripheral 326
Arterio-sclerosis of the pulmonary vessels 219
Arterio-sclerotic gangrene, postural treatment of
 146
Arteritis obliterating arterial resection in 141
Arteritis pulmonary, 381
Arteritis typhoid curable 30
Arteritis ammonium ortho-todxybenzoate in
 233
Arthritis tonsillotomy in, 436
Asthma, adrenaline and blood pressure 50
Asthma, anaphylactic relieved by bleeding 225
Asthma and hay fever 250
Asthma oral administration of pollen in, 37
Asthma Pirquet and Wassermann reactions in
 158
Atrophy, acute yellow, following clonophen
 administration 237

ARTILLO O. Z. Granulomatosis siderotica of the
 spleen, 236
AUBREY E. Angor ocularis 317
AUBERTIN O. Agranulocytosis 117
AUBRICHO L. Familial anaemia with
 splenomegaly in infancy 493
Auto-haemotherapy in herpes zoster 476
Azospermia surgical treatment of 162

B.

BACOF K. J. Pirquet and Wassermann re-
 actions in asthma 158
Bacilluria coli treatment of, 59
Bacillus abortus pathogenicity of for man 302
Bacillus botulinus in Scottish soils 322
Bacillus Calmette-Guérin Vaccination of cattle
 with 172—Inoculation of Pirquet negative
 persons with 490
Bacillus paratyphosus A isolated from epidemic
 jaundice 213
Bacillus pseudotuberculosis rodentium and
 B. pestis relation of 235
Bacillus pyocyaneus meningitis due to 455
Bacchoe traumatic prostatic 363
Bacteria, extraction of toxic substances from
 444
Bacteria living passage of through the
 intestine 256
Bacterial allergy in recurrent erysipelas 154
Bacterial differentiation surface tension
 measurements in 398
Bacterium pseudotuberculosis rodentium sero-
 logical study of 532
BAILY J. Local vaccination against rabies 24
BAINBRIDGE, W. S. Abdominal adhesions 388
BALACANTU V. Venous blood pressure in hyper-
 plasia 239
BING B. Fever in gastritis and duodenal ulcer
 139
BARDY A. Diagnosis of the foetal age from
 ossification centre, 354
BARKER, L. F. Treatment of endocrine disorders
 in infancy and childhood, 345
BARRAL, P. Contraindications to the use of
 salvarsan 196
BARRAS, W. Stovaine analgesia, 229
Bertholin's gland tuberculosis of 528
BASCH Trichophytriosis dermatitis 17
Basophilic punctate in the lead treatment of
 malignant disease 173
BAUER, J. H. Incubation period of yellow fever
 in the mosquito, 175
BUDMANS J. Differential diagnosis between
 acute appendicitis and epididymitis 142
BECKER J. Triammas due to scar formation 8—
 Mercury lamp treatment of whooping-cough
 284
BESON B. B. Auto-haemotherapy in herpes
 zoster 476
BEGO R. Campbell Home treatment of common
 urinary complaints 389
BELL, W. Blair. The malignant functions of the
 chorion epithelium, 258
BELLU A. Wounds of the vagina from colitis
 231
BELMONT, A. C. Diagnosis of lobar pneumonia
 in children 324
BELTRAMI P. The precipitating and protective
 process of anti-anthrax serum 486
BENEDICTI P. Arterio-sclerosis of the pulmonary
 vessels, 219

BENGOLZA, A. J. Diverticulum of the duodenum 76
 BERARD L. Surgical treatment of exophthalmic goitre, 186
 BERINO, F. Treatment of early cerebro-spinal syphilis 313
 BERTRAND J. Administration of ergosterol in rickets 501
 BERTRAND P. Indications for appendicostomy 246
 BERTWISTLE, A. P. Elephantiasis 516
 Besredka's antilyris 436
 BESSEYAS, J. The complement fixation test in Wells disease, 47
 BETTAZZI G. Wounds caused by coping pencils 405
 BIFULCO C. Surgical treatment of typhoid perforation 77
 Biliary intestinal anastomosis for obstructive jaundice, 242
 BINKLEY G. E. Radium treatment of rectal cancer 350
 BINNEY H. Treatment of empyema following pneumonia 311
 BIRKHAUO K. E. Bacterial allergy in recurrent erysipelas 154
 Bismuth naphthamine sulphonate in syphilis 346
 Bismuth as a diuretic, 312
 Bismuth preparation an aromatic 165
 BIZB P. R. Streptococci in complications of scarlet fever 48
 BLACK, J. H. Oral administration of pollen in asthma 37
 Bladder calculi in young children 366
 Bladder irritability of the 152
 BLACQUETTER P. Anaphylactic asthma relieved by bleeding 226
 BLANC, H. Renal tuberculosis 10
 BLANCHET, P. Associated movements in organic cerebral hemiplegia, 461
 BLANKENHORN M. A. Clinical aspects of alcoholism 269
 Blastomycosis carbon dioxide snow in, 15
 Blastomycosis systemic, 371
 BLATT M. L. Acute tuberculous pericarditis 53
 Bleeding after colitis in cervical cancer 464
 BLOEDORN W. A. Cardiac contraindications to ephedrine administration 410
 Blood changes During malarial paroxysms 465
 —During surgical anaesthesia 623—In scarlet fever 23
 Blood changes in scarlet fever 23
 Blood coagulability action of ethyl alcohol on 412
 Blood lecithin action on 233
 Blood meningeal permeability and physical changes in the 301
 Blood pressure aethan and adrenaline, 50
 Blood pressure in tabes dorsalis variations of 94
 Blood pressure, venous, in hyperplasia 239
 BLUM, J. The late oculomotor syndrome of epidemic encephalitis 218
 BOUNDARY W. W. Uncertainty of cholecystography, 348
 BOONING A. B. Rhinopharyngitis in infancy, 128
 BOWEN L. R. Traumatic prostatic backache 363
 Bone diseases bone marrow transplantation in 265
 Boltz reaction the, 399
 BOURGEOIS The spleen in alcoholic cirrhosis 95
 BOURNE, W. Chloroform and the hepatic function 137
 BOYD Gladys L. Nephrosis in children 306
 BOYER L. B. Paratyphus A isolated from epidemic jaundice, 213
 BRANCH J. R. B. Intestinal tuberculosis causing obstruction 310
 BRATT J. F. Pleurisy as a complication of pulmonary tuberculosis 96
 BRATOSCH MURRAY A. Familial pylorospasm 437
 BREMOND Sulfarsenol as a preventive of puerperal infection, 58
 Bronchiectasis dry 492
 Bronchitis ether treatment of 525
 Broncho-pneumonia in infancy 128
 Broncho-pulmonary mycosis 360
 BROOKFIELD R. W. Functional basophilia in the lead treatment of malignant disease 173
 BROOKS G. Antityphoid inoculation 470
 Brow presentation. See Labour and Presentation
 BROWN N. S. Bismuth as a diuretic 312
 Brucella abortus and Brucella melitensis serological differentiation of 467
 BRUSHFIELD T. Hemiplegia with extensive naevus and mental defect 237
 BUBERT H. M. Subacute combined sclerosis 147
 BUCURA C. Treatment of inflammatory adnexal diseases 606
 BULTEMAN H. Insulin treatment of uterine haemorrhage 276
 Bundle-branch block physical signs in 97
 Burns, a conservative operation for 423
 BURDEN V. G. Pyloric achalasia and peptic ulcer 407
 BURGESS, N. Calcium metabolism in diseases of the skin 279
 BURKARD Early diagnosis of pulmonary tuberculosis 401
 Burns treatment of 266
 BURRELL L. S. T. Syphilis and tuberculosis 469
 BURY F. The organic content of human enamel 113
 BUSCHKE A. Toxic effects of thallium 261
 BUSTON J. B. Bacillus botulinus in Scottish cattle 322
 BUTYLA, P. A. Sanocrysin in tuberculous meningitis 145

C.

CABOCH, H. Indications for treatment in tuberculous laryngitis, 412
 Caecal volvulus in pregnancy 440
 Caesarean section, abdominal, local anaesthesia for 483
 CAFFIER, P. Cervico-vaginal fistula, 203
 Calcium chloride injections for treatment of epididymitis, 456
 Calcium metabolism in diseases of the skin, 279
 Calcium salts and carbon inclusions in treatment of pulmonary tuberculosis 224
 Calculi bladder, in young children, 366
 Calculus impacted in the female urethra 396
 Calculus, pancreatic 337
 CAMEROX A. T. Pre-operative treatment of Graves disease 434
 CAMURATI, M. Fracture statistics 290
 Cancer of breast prognosis in 101
 Cancer of the cervix. Bleeding after coitus in 464—Cystoscopy for 485—Commencing diagnosis of, 170
 Cancer of the cervix uteri, 277
 Cancer etiology of, 321
 Cancer, lead treatment of, punctate basophilia in 173
 Cancer of lower lip 429
 Cancer naevus, and melanoma-sarcoma 34
 Cancer of the pancreas 267
 Cancer of the rectum 119—Radium treatment of 350
 Cancer of the stomach, perforation in 100
 Cancer transmissibility of 78
 Cancer of ureter primary 245
 Cancer of the body of the uterus 278 419
 Cancer of uterus results of operations for 205
 Cancer of vulva 256
 Carabelli's tubercle, the significance of 51
 Carbon and calcium salts inhalations in treatment of pulmonary tuberculosis 224
 Carbon dioxide anaesthesia. See Anaesthesia
 Carbon dioxide snow in blastomycosis 15
 Carcinoma. See Cancer
 Cardiac contraindications to ephedrine administration 410
 Cardiac hormones, 67 68
 Cardiac neurosis remedial measures for 247
 Cardiac problems, common 307
 Cardiac therapy in pneumonia 144
 Cardiac. See also Heart
 CARMICHAEL, E. A. Stramonium in Parkinsonian rigidity 521
 CANNON Diabetes of ovarian origin, 87
 CANOLI Diabetes of ovarian origin 87
 Carcinoid common temporary ligature for haemorrhage following tonsillectomy 187
 CARP, L. Ganglia, 454
 Carriers in Vincent's angina 286

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

1 Meningitis in Numps

J. LAFFIENS (*Rev. Méd. Suisse Rom.*, April 25th, 1928, p. 420), who records a personal case, illustrates the rarity of this complication by the fact that he found only 37 other cases on record. Of those, only 3 were adults, aged from 19 to 23, 2 being soldiers. Of 19 cases in which the sex was stated 15 were males. In another 19 cases in which the date of onset was stated the meningelial symptoms preceded the parotitis in 5, accompanied it in 4, and followed it in 10. The symptoms may be mild or very severe. In 25 cases in which lumbar puncture was performed a moderate or slight lymphocytosis was found. In only 3 instances was note made of the amount of albumin, which was increased in each case. The prognosis is generally good, only 2 of the cases were fatal. The necropsy of one of the latter, recorded by Acker, showed congestion of the convexity of the brain, hydrocephalus, and layers of fibrin at the base. No changes were seen in the spinal cord. Laffiens's patient was a boy, aged 12, in whom the meningelial symptoms and parotid swelling appeared on the same day. A slightly turbid cerebrospinal fluid showing lymphocytosis was removed under pressure, and rapid recovery ensued.

2. Paroxysmal Tachycardia Flutter and Fibrillation

E. GÉRAUDEL (*Arch. des Mal. du Cœur*, May, 1928, p. 273) recapitulates the generally accepted views concerning paroxysmal acceleration of the heart's action. Such paroxysms have been regarded as being of three kinds—sinus or nodal tachycardia, auricular flutter, and auricular fibrillation. The author considers, however, that the first group, in which a ventricular response follows every auricular contraction, is identical with auricular flutter, and supports his contention by two series of electrocardiograms taken over several years. The cases described were those in which periods of tachycardia, of quiescence and of variable irregularity succeeded each other from time to time. Electrocardiograms taken during each of these periods showed that during the attacks contractions were originating from either the normal pacemaker or an ectopic one. During quiescence the tracings proved the presence of 2:1 auricular flutter, and in the times of variable rhythm brief periods of 2:1 flutter alternated with groups of rapid contractions representing 1:1 flutter. The stages of transition between one condition and another were also demonstrated by the electrocardiograph. This conception of the true nature of paroxysmal tachycardia has been tested by the study of 97 cases during the last four years. No case of sinus or nodal tachycardia was found which did not conform in type to the cases described, always there was shown to be present at times a 1:1 auricular flutter. In his consideration of the relationship between auricular fibrillation and flutter Géraudel adduces evidence to show that the difference between the two states is merely one of degree—the essential feature in each case is rapid auricular action, this is easily demonstrable in flutter, and it is believed that absence of P waves in the electrocardiogram of fibrillation is misleading in that their absence does not necessarily indicate failure of auricular contraction, since the form of P like that of the ventricular complex, may be influenced by other factors than alteration in muscular activity. Both paroxysmal tachycardia and fibrillation seem, therefore, to be of like origin, arising from a condition of rapid auricular contraction which may be either regular or irregular.

3. The Late Results of Sanocrysin Treatment.

KJER PETERSEN and V. PETERSEN (*Ugeskrift for Læger*, April 12th, 1928, p. 347) have collected the sanocrysin statistics of various Danish hospitals and sanatoriums during the past four years, and of 136 cases they have eliminated 38, either because the patients had no tubercle bacilli in the sputum, or they could not be traced, or they had received only one or a few injections, or the treatment was still being continued. Of the remaining 98 only 12 were improved, 21 were classified as unchanged, 28 as worse and 37 as dead. With the exception of a few cases of fibrotic disease of long standing, the prognosis for which is relatively good, most of the patients classed as improved belonged to Turhan's first and second stages—that is, stages in which the chance of recovery is comparatively good in ordinary circumstances. The authors conclude that there is no case in their series showing such results from sanocrysin treatment as to

warrant its being credited with any therapeutic virtue, and they consider that the hope that sanocrysin would result in patients getting rid of the tubercle bacilli in their sputum and ceasing to be infectious has proved to be illusory.

4. Precordial Pain and Epidemic Encephalitis

J. C. M. LOURNIER, A. GARRA, T. ROCCA, and J. MONESTIER (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, March 15th, 1928, p. 450) state that pain is a well recognized symptom in lethargic encephalitis. It may be localized in certain viscera and simulate various affections, such as appendicitis, renal colic, or intestinal obstruction, until somnolence or the appearance of hiccup or myoclonic movements in other muscles than the diaphragm reveals the true nature of the disease. These pains show a predilection for the abdominal organs, but have also been noted in the thoracic region by Esbach, who has recorded a case of retrosternal pain, and Lanby one with symptoms of angina pectoris. The present authors' case was that of a man, aged 44, in whom the onset of epidemic encephalitis was preceded for three days by a sort of sensory aura consisting in precordial pain which radiated along the left ulnar nerve. The recurrence of the same symptoms and with the same duration when the patient had a relapse of the encephalitis excluded the possibility of a mere coincidence.

5. Diphtherial Infection of the Scrotal Contents

G. MARTIN (*Journ. Amer. Med. Assoc.*, April 7th, 1928, p. 105) reports the case of a man who for twenty-six years had had a scrotal swelling without its causing him any inconvenience. A week before admission to hospital it became acutely inflamed and signs of suppuration appeared, 140 c.cm. of pus was withdrawn and a pure culture of virulent diphtheria bacilli obtained. Subsequently 50 c.cm. of sanguino-purulent matter was evacuated and greyish membrane protruded from the sinus, 15,000 units of antitoxin were given intramuscularly and considerable improvement ensued. No similar cases appear to have been recorded in urological literature. There had probably been two infections within the tunica vaginalis, diphtheria being superimposed upon an older one which had reached the scrotum through the blood stream.

Surgery.

6. Kümmell's Disease

W. H. M. TELLING and G. F. WALKER (*The Caduceus*, February, 1928) describe the train of events which constitute Kümmell's disease or post-traumatic spondylitis, a delayed slow collapse of a vertebral body subsequent to injury. From a study of twelve cases it is shown that the initial injury to the back, either direct or indirect, can be extremely varied in nature and severity. After a short period of rest and slight disability, a latent period, averaging six months, supervenes in which the patient experiences no disability whatever. This is followed by the collapse of a vertebral body the symptoms of which begin insidiously with pain in the back, progressively becoming worse, it is associated with girdle pains due to the unhinging of the bony column, and with paraplegia, sensory loss, and sphincter disturbance due to interference with the cord. The collapse of the vertebra in the form of a wedge produces an angular kyphosis. The differential diagnosis of this condition from Pott's disease rests on the fact that the patient is otherwise quite healthy and that there is no abscess formation nor any change associated with granulomatous disease, the diseased body, viewed laterally, is sharply wedge shaped without any signs of erosion or irregularity or cartilage invasion. Treatment consists in supporting the falling vertebra by a leather or plaster jacket the prone position on a Bradford frame, or, in selected cases, a spinal bone graft. Prognosis is difficult to assess, but if orthopaedic treatment is adopted at the outset the authors consider that the inability to do full work will last for about two years.

7. Appendicitis in Middle Age.

E. M. FITCH (*New England Journ. of Med.*, April 8th, 1928, p. 348), who has collected 37 cases of appendicitis in persons more than 50 years of age, maintains that the disease is as common in people over 50 as in children under 10, and about the same as in the age group 40-50. Of the 37 patients, 24 were males and 13 females. In very few cases was there a history

of direct traumatism from outward violence. In a series of 765 cases of appendicitis at all ages only one definite foreign body was found. Eight patients died—a mortality of 21.6 per cent, one death occurring between 50 and 60, six between 60 and 70, and one over 70. The cause of the relatively high death rate was the much greater severity of the attack, in which the pathological findings were more extensive and the circulatory changes pronounced.

8 Permanent Colostomy

C. H. MAYO and C. F. DIXON (*Annals of Surgery*, May, 1928, p. 711) believe that a permanent colostomy is a fairly common surgical procedure. The ideal stoma is one which can be seen and is easily managed and cared for, the anterior stoma has been found to be more satisfactory than any other type. They describe an operation which provides sufficient control without cumbersome apparatus or the risk of hernia. An incision is made just to the inner side of the left anterior superior spine parallel with Poupart's ligament. The descending colon is brought out and the peritoneal pocket lateral to the sigmoid mesentery is closed with a purse string suture, thus preventing herniation of the small intestine. The cut edges of peritoneum are then sutured together through the mesocolon, and a muscle flap from the lateral oblique is sutured through the gap to the edge of the rectus. After sewing of the external oblique a skin flap is cut and brought through the mesocolic opening and sutured in position. Three days later a small opening is made in the bowel to allow the escape of gas, and on the seventh day a wedge-shaped piece of colon is removed. Irrigation can be carried out through both openings, the muscle flap gives satisfactory control, and there is usually one action of the bowels each morning.

9 Trismus Due to Scar Formation

J. BECKER (*Med. Welt*, May 5th, 1928, p. 631) describes a case of trismus which was not due to temporomaxillary synostosis and which did not require resection of the bone. The patient attempted suicide by shooting himself. The bullet entered just above the right zygoma and was removed at a point about 2 cm. behind the outer commissure of the left eyelids, having traversed the lobe of the left ear, of which about 4 cm. was removed. There was no visible defect nor evidence of injury to the nervous system. During treatment severe trismus developed, so that the mouth could not be opened more than 0.75 cm. Before the operation the incisors could not be separated more than 3 mm., but after operation this was increased to 6 mm. The final result was that the incisors could be separated to the normal extent and the mouth could be opened fully. It was found that the temporal muscle had been so injured that a large mass of scar tissue interfered with its action. On the left side masticatory movements did not produce a definite muscular swelling. The operation was quite simple. Through an incision parallel with the lower border of the zygoma the osseous process was exposed, this was divided with a chisel and the tendinous portion of the temporal muscle was removed. This permitted free masticatory movements, and the patient made a complete recovery.

10 Renal Tuberculosis

H. BLANC (*Journ. de Méd. de Bordeaux*, April 25th, 1928, p. 29) believes that renal tuberculosis is more common than is generally supposed, unless the urinary symptoms can be otherwise explained it should always be considered a possibility. Most of these patients, at any rate in the early and therapeutically most hopeful stages, do not look ill and are often well nourished. The symptoms may be those of cystitis (eight out of the ten cases), pyuria, haematuria, or lumbar pains. Each case of spontaneous, relapsing, and resistant cystitis should be suspected of being tuberculous and indicative of cystoscopy, except in acute menorrhagic cases. The irritability of the bladder is generally reflex from the kidney and is not due to tuberculous disease of the bladder. Inability to find Koch's bacilli in the urine does not exclude a tuberculous kidney. Having decided that the kidney is tuberculous the only treatment is nephrectomy, unless this is contraindicated for other reasons. Although the disease may become quiescent no real cure ever occurs, the symptoms may subside owing to destruction of the affected kidney. Blanc adds that there is room for medical treatment in what is called medical tuberculosis where there is a tuberculous infiltration of the organ without open lesions or pyuria, or in bilateral tuberculosis where nephrectomy is impossible, or after nephrectomy as a prophylactic. In the rare cases of renal tuberculosis in children medical treatment is possibly advisable. In addition to measures of general hygiene and diet (not exclusively milk) the author speaks highly of methylene blue, not only internally, but locally as an instillation for the bladder.

Therapeutics.

11 Treatment of Diphtheria Carriers.

ACCORDING to G. P. LINGENFELTER (*Colorado Medicine*, March, 1928, p. 92, L. C. Donnelly, in 1922, was the first to report a large series of diphtheria carriers treated by ultra violet rays, which were projected on to the tonsils through a hollow metal applicator for from three to five minutes. Of 40 cases, 20 were rendered sterile by one application, 16 more by two, and the remaining 4 by three. In treatment of the nose 10 to 15 drops of a 10% solution of chlorid solution were applied to the mucous membrane and the nasal applicator used for ten minutes, during which time it was slowly inserted and withdrawn. Subsequently F. C. Turner obtained successful results by ultra violet treatment, either alone or combined with mercuriochrome. Lingenfelter himself has treated 44 carriers aged from 5 to 57 by a combination of water cooled applications with general body radiations from an air cooled lamp, exposing the entire person daily and gradually increasing the dosage so as to build up resistance and increase metabolism. Of the 44 cases, 42 were released with negative cultures after three to twenty seven treatments ranging from two and a half minutes' initial exposure to twenty minutes' final exposure with the air cooled lamp, to fifteen seconds to two and a half minutes with the water cooled lamp. The results appeared to be superior to those obtained by x-rays, and very much better than those following any other local applications. It is said to be essential, however, that the treatment should be performed in hospital, where sanitation and personal hygiene can be supervised.

12 Plasmochin in Malaria

COMPARING the effects of plasmochin and quinine in the treatment of malaria, P. V. KARAM CHANDANI (*Indian Med. Gaz.*, May, 1928, p. 249) gives a summarized account of eleven cases of malaria in which plasmochin was given with a view to studying its effects on the leucocytes, the gravimetric, patients showing an idiosyncrasy for quinine, and on intractable cases when quinine administration had little effect. Since this drug causes leucopenia, which should be avoided in pneumonia, two cases of lobar pneumonia complicated with benign tertiary malaria were selected and treated the one with plasmochin, the other with quinine. After three days' treatment no parasites were found in the former, while they still persisted in the latter. Sodium molybdate injections had also been given to raise the leucocyte count. In two cases of heavily infected malaria, the one treated with plasmochin and the other with plasmochin tablets, the blood became parasite-free in five and three days respectively. In one case of pregnancy with co-existent malaria, which had proved to be either idiosyncratic or intractable to quinine, were successfully treated by plasmochin with no ill after effects. In a case of severe malaria and two of a chronic type which had not yielded to quinine treatment, the administration of plasmochin gave excellent results. The author mentions thirteen other patients whose ages ranged from 16 days to 60 years, and who were successfully treated with this drug. In no case did cyanosis or any other untoward symptom occur. The daily dose of plasmochin for adults was never more than 0.6 gram, smaller doses according to age being prescribed for the younger patients.

13. The Subdural Injection of Antitoxin in Tetanus

R. GOEDECKE (*Centralbl. f. Chir.*, April 28th, 1928, p. 1027) describes nine cases in which tetanus was treated by the subdural injection of antitoxin. After lumbar puncture 20 ccm. of cerebro-spinal fluid is withdrawn, followed by the subdural injection of 100 units of antitoxin, both parietal regions are trephined and a subdural injection of 100 units of antitoxin serum is given on each side. The subsequent medicinal treatment follows the usual lines—namely, the administration of antitoxin, magnesium sulphate solution (usually subcutaneously), and sedatives such as chloral hydrate and morphine or scopolamine. In addition to the parietal subdural injections in two severe cases 100 units of antitoxin were injected into the cisterna cerebello-medullaris, after the withdrawal of 20 ccm. of cerebro-spinal fluid. One of those patients recovered from tetanus, but developed Jacksonian epilepsy. Several years later the general health was good and intelligence was unimpaired, but the epileptic fits recurred every eight or nine weeks. Goedecke reports that of the nine patients four were cured, one died later from sepsis, and four died from tetanus. This series corresponds generally with the majority of those published already on this method of treatment. All writers report occasional recoveries, but Goedecke concludes that there is no evidence that the subdural injection of antitoxin is superior to the older methods of treatment.

14 Treatment of Pruritus Ani

M F CRIADO (*La Med Ibera*, April 7th, 1928, p 387) states that the local treatment of pruritus ani varies with the following types of lesions (1) complete absence of any objective lesions, (2) eczematization, (3) lichenification, (4) fissures. In the absence of any obvious lesions the parts should be kept scrupulously clean, but it should be remembered that soaps, especially those strongly alkaline, are injurious. Before defecation the patient should smear the parts with some greasy preparation then wash them with a slightly astringent solution, carefully dry them with a towel, dust them with an inert powder, apply an ointment, and place a slip of gauze between the buttocks. In cases of eczematization the vascular condition should be relieved by application of inert powders, such as zinc oxide, boric acid, or talc, or, if these powders are not well tolerated, ointments such as zinc oxide or vasoline should be applied. In lichenification, preparations of tar, green soap, or chrysophanic acid are indicated, and in very obstinate cases the application of x rays. Fissures are best treated by cauterization with silver nitrate in 5 to 10 per cent. solution.

Dermatology.

15 Carbon Dioxide Snow in Blastomycosis

H M HEDGE (*Journ Amer Med Assoc*, April 28th, 1928, p 1367) advocates the use of carbon dioxide snow in the treatment of blastomycosis, and he reports two localized cases which yielded rapidly and completely, remaining without any sign of recurrence for over a year. A cylinder of carbon dioxide is laid at an angle with the valve down wards, over the valve is fitted a square of chamois skin shaped like a receiving bag, and the gas is collected in this in the form of snow when the valve is opened. This snow is then packed into an ear speculum and tamped down into a firm pencil which can be held with a small piece of chamois skin and applied firmly to the surface of the lesion for from ten to fifteen seconds. In the cases reported, one with a lesion on the cheek and the other on the right foot, this method was tried after various others had failed, with the result in each case that a crust formed in a few days, leaving a clean granulating ulcer on removal at the end of a fortnight. It gradually healed with only a slight scar, and without any sign of recurrence after more than a year had elapsed. Hedge considers that these results justify the inclusion of this method among other approved treatments for the condition.

16. Anomalous Forms of Recklinghausen's Disease.

J J ELLER (*Arch Derm and Syph*, May, 1928, p 648) refers to the previous article on this subject by F. Wise and J. Eller (see *Epitome*, 1926, vol 1, para 228), and reports further cases. He concludes that there is no doubt that an abortive incomplete, or pre tumour type, of Recklinghausen's disease exists, pigmented areas appearing in place of the skin tumours in one case and together with them in another. He adds that this variety of the disease is usually encountered in one or more children of a family in which either parent has the typical neurofibromatosis of the skin, but a pigmentary eruption, without tumours, may also occur in adults. It is suggested that as the disease progresses tumours eventually make their appearance.

17 Trichophytic Dermatitis

P RAVIET, BASCH, and RABEAU (*Presse Med*, May 16th, 1928, p 609), describe an epidemic of dermatitis due to the *Trichophyton necans radicans* which occurred among a number of female clerks. In all the cases, 99 in number, the cutaneous lesions were limited to the glabrous regions of the body, especially the uncovered portions of the neck the summit of the thorax, and the arms. The primary source of infection apparently was a cat, and the epidemic was evidently propagated by the interchange of office apparel and dissemination through clothes disinfected during work hours, this accounting for the seat of the eruption. Fifty seven of the cases presented typical forms of herpes circinatus the lesions consisting of red or reddish brown infiltrated patches, often showing vesico-papules or a folliculitis in different stages of development the latter resembling pityriasis keratosis. In some patients only one lesion occurred, and in others many, often differing in aspect from each other. The remaining 42 patients presented multiple forms differing from the typical trichophytic type, and simulating psoriasis, pityriasis, and lichen planus. The striking points in this outbreak were the rapidity of evolution and limitation of the lesions the grouping of the constituent elements, the absence of generalization, and very often the presence of intense

pruritus. In all the cases the diagnosis was confirmed by smear and cultural examinations, and by the cutaneous reactions following intradermal injections of trichophytin. The authors emphasize the diagnostic value of the latter test, and refer to Sabouraud's law relating to the specificity of trichophytin, which these cases apparently verify.

18 Lichenification due to a Trichophyton Infection.

In a case of lichenification in a woman, aged 38, reported by MILIAN and T. PHOTIROS (*Bull de la Soc Française de Derm et de Syph*, March, 1928, p 212) the eruption first appeared on the lower right side of the neck as a very irritating small red spot the size of a pea. Three or four days later larger squamous patches developed, which itched intensely, causing much scratching. On examination the eruption was found extending to the clavicles on both sides of the neck, and consisted of rose red patches as large as the palm of the hand. On the edges some small bright papules, simulating lichen planus, were seen. After two days two large dark red patches, covered with small scales and surrounded by disseminated papules, appeared in the left axilla, and a similar patch in the right one. A diagnosis of trichophytic lichenification was now made. Tincture of iodine was applied to the left side of the neck as a test measure, and two days subsequently, though there was great improvement in these lesions and the itching had completely ceased, some red, itching papules were seen on the extensor surfaces of both forearms. Iodized alcohol in 1 per cent strength was now used with apparent improvement, this was replaced by an ichthyol paste, and later by a tar ointment. Cure was effected, and when last seen the patient complained only of the slight irritation caused by the tar. At the age of 5 the patient had an attack of pityriasis. At the present time she was living alone, owned no domestic pets, and none of her fellow workers suffered from a like affection. *Trichophyton granulosum* was isolated from the scales, and a possible cause of infection was a new fur which had been worn some three months previously to the appearance of the eruption. Brocq distinguishes two forms of lichenification primary, without any visible, local, cutaneous cause, and secondary, the result of tegumentary reaction to some affection, as prurigo or eczema.

Obstetrics and Gynaecology.

19 A Dental Source of Puerperal Infection.

According to H. SACHS (*Zentralbl f Gynä*, April 21st, 1928, p 991) it is of importance that the laity should be disabused of the popular notion that dental treatment during pregnancy is fraught with danger to mother or foetus, on the contrary, treatment of dental and oral sepsis at this time is of the greatest importance in the prophylaxis both of morbid renal conditions and of puerperal infections. Such sepsis may act as a source of infection by the blood stream or may lead to direct infection of the genital tract by the patient, nurse, or physician. The case is related of a woman who, four days after spontaneous delivery, during which neither rectal nor vaginal examination was performed, showed signs of endometritis and pyrexia. These continued until the twenty third day and the lochia contained *Streptococcus viridans* and *Staphylococcus haemolyticus*. The temperature fell and the patient improved after the extraction at this time of several carious teeth, which gave issue to pus containing the same organisms as were present in the lochia. The infant suffered from rhinitis, and a nasal swab also contained the same cocci.

20. Vaginal Hysterectomy

R. PETIT (*La Gynécologie*, March, 1928, p 129) reports 123 consecutive successful cases of vaginal hysterectomy. He describes his own technique in detail, illustrating the stages of the operation by photographs. He enumerates the advantages of this method as (1) minimum amount of shock, obviated because there is no manipulation of the intestine, (2) reduction of the danger of infection because the operation is extra peritoneal, (3) after the seventh day the patient can get up and walk, (4) absence of external scar and therefore prevention of ventral hernia, (5) reduction of the possibility of adhesions, (6) rapidity of the operation. Of his 123 cases, 75 were fibromas, 17 fibromas with non suppurating adnexa, 11 with suppurating adnexa, 4 prolapse, and 16 neoplasms of varying degree. All these patients were able to be up on the seventh day, and they recovered from the operation without incident. The author considers vaginal hysterectomy the operation of choice in elderly patients who have been weakened by previous haemorrhage, especially where there is infection of the adnexa, for fibromata when the size is not excessive, and in complete prolapse of the uterus after the menopause. The operation is contraindicated when the

fibromas are too large to be delivered without cutting into them, when multiple adhesions are expected, especially in connexion with the appendix, and when myomectomy is required. With regard to the sixteen cases of neoplasm reported, the number was too few to allow any definite conclusions to be drawn, but it is stated that all the patients recovered from the operation without shock and had remained well for varying lengths of time.

21 Appendicitis complicating Pregnancy

G. I. MILLER (*Med. Journ. and Record*, May 16th, 1928, p. 552) states that, owing to the large amount of lymphoid tissue in the appendix and its dependent position, this organ is a constant reservoir of bacteria, and during gestation the patient may have a primary or recurrent attack of appendicitis. In pregnancy a recurrence is more likely to occur because the body generally is weakened and has lessened resisting powers, moreover, the progressively enlarging uterus causes traction on existing adhesions and pressure on the appendix. An infection in a remote part of the body will predispose to a bacterial invasion of the appendix, thus a pre-existing alveolar or tonsillar condition may become activated, virulent streptococci reach the appendix, and a local inflammation ensues. The diagnosis of appendicitis during pregnancy is usually simple, but the condition must be distinguished from pyelitis, renal colic, ureteral stricture, hydronephrosis, ovarian cyst, and ectopic gestation. The blood picture may not be a great aid, since a leucocytosis of 12,000 is not pathological, but when a high total count is coupled with a high polymorphonuclear count the diagnosis is definite. After other abdominal lesions have been excluded, pain in the right lower quadrant of the abdomen during any stage of pregnancy is an imperative indication for immediate operation. The prognosis is good for both mother and child when the operation is performed without delay and before suppuration and rupture of the appendix, and in the absence of these there should be no mortality. The operation is much easier during the first half of pregnancy before the ovum and appendix have become displaced. The ideal time to operate is before conception has occurred, but if pregnancy is present the period of gestation should not influence prompt operation, the acuteness and virulence of the infection being the determining factor. Abortion and maternal death depend on the virulence of the infection, the period of gestation, and prompt surgical intervention. The operator should confine himself to the appendix alone, and avoid handling or even touching the uterus and adnexa. Miller details his results in 59 cases of appendicitis complicating pregnancy, 37 being intrauterine and 22 extrauterine.

22 Diathermy in Gynaecology

G. GELBHORN (*Journ. Amer. Med. Assoc.*, March 31st, 1928, p. 1005) discusses the employment of diathermy in gynaecology for pelvic inflammations, gonorrhoea, non-infectious gynaecological conditions, and cancer of the uterus. In pelvic inflammations he uses an outer ribbon electrode encircling the waist of the patient and a vaginal electrode surrounding the cervix, occasionally a rectal electrode was found more suitable. He warns against starting with a too intensive application, and suggests that, as a general rule, a temperature of 115°F., registered by the thermometer within the vaginal electrode, is the standard to be aimed at. Each application lasts from twenty to thirty minutes, and the treatment is repeated at intervals of three days. The method is contraindicated in acute infections, and even in subacute and early chronic stages care is necessary, the patient's temperature being watched, and the treatment stopped if there is any rise. The author suggests that diathermy might also give assistance in the treatment of chronic salpingitis. In two cases of gonorrhoea which had resisted all therapeutic efforts prompt and permanent cure followed urethral and intracervical diathermy. Gelborn emphasizes the importance of using this powerful remedy with great caution.

Pathology.

23 Changes in the Blood in Scarlet Fever

J. SABRAZÉS (*Arch. des Mal. du Cœur*, April, 1928, p. 193) states that leucocytosis is the rule in scarlet fever, especially in malignant forms. Even in moderate attacks the total number of white cells not infrequently exceeds 15,000 to 20,000. This leucocytosis, which occurs to a less degree in mild attacks, is chiefly manifested by an increase in the number of the neutrophil polymorphonuclears. As the temperature falls the number of leucocytes diminishes but does not become normal until desquamation is finished. Not infrequently a few neutrophil myelocytes appear in defer-

rescence. The polymorphonuclears often show toxic changes in their nuclei and cytoplasm. It is in scarlet fever that basophil inclusion bodies, first described by Barralou in 1910 and later by Döhle and many others, are very frequently found in the cytoplasm. During the first few days of the disease 95 per cent. of the polymorphonuclears may show from one to three inclusion bodies. In mild cases they persist for four to six days, and in severe attacks for three to four weeks. Their duration may be prolonged by the appearance of complications. The inclusion bodies described by Anato are much less frequent. During the first few days the eosinophils are normal or decreased in number, but subsequently they show a considerable increase in proportion to the rise in the leucocytosis. In fatal cases eosinophils may be entirely absent. As regards the red corpuscles, marked anisomiasis is not exceptional, and occasionally nucleated red cells are found. The sedimentation rate is increased during the first few days of the disease, and then gradually becomes normal by the end of the fourth week. The surface tension of the plasma, as von Koss (*Labor.*, January 28th, 1928, para. 107) has shown, falls more or less during the first week.

24 Local Vaccination against Rabies.

P. REMLINGER and J. BAILLY (*Ann. de l'Inst. Pasteur*, April 1928, p. 349) remark that neither the cellular nor the humoral theory of immunity is altogether satisfactory in explaining immunity to rabies. Though in general there is a parallelism between the development of rabid animal bodies and the establishment of immunity, there are exceptions. Some persons who have been bitten and have been treated fail to develop immune bodies, and yet do not contract the disease, conversely, there are persons who develop immune bodies, and who yet die of the disease. Similarly, while there are animals, such as the cat and the viper, which are refractory to rabies, their serum destroying the virus, there are others such as the tortoise, which are naturally resistant to rabies, though the serum has no rabicidal action. The authors, therefore, asked themselves whether immunity was possibly a local phenomenon, as is largely maintained by Borodko. To test this they proceeded to vaccinate a number of guinea pigs cutaneously with dried or etherized virus, and subsequently to test their resistance to cutaneous or intra-muscular injection of fixed or street virus. In the process of vaccination the abdominal skin was shaved and the virus was rubbed in vigorously for some minutes with a tooth brush, the animal was then maintained in the recumbent posture for half an hour to allow the virus to dry on to the skin. The results were not very satisfactory. The authors obtained evidence that cutaneous vaccination, if repeated seven or eight times, did increase the resistance to inoculation with active virus but the superiority over the controls was not very marked. They consider that the local vaccination should be not of the skin but of the brain. In support of this they quote Mario and Maternich's results, which showed that rabbits vaccinated by the meningeal route became, after three injections completely refractory to intra-cerebral inoculation with fixed virus.

25 The Relation of *Leptospira autumnalis* to *L. icterohaemorrhagiae* and *L. hebdomadis*

ACCORDING to G. J. STÉFANOPOULOU and S. HOSoya (*C. R. Soc. de Biologie*, May 18th, 1928, p. 1317) the autumn fever of Japan, sometimes called "akiyami," occurs in epidemic form in certain districts during the months of August to October. Clinically it is characterized by fever, muscular pains, anisæmia, insomnia, conjunctival congestion, a mild degree of jaundice, and slight general lymphadenitis. The fever lasts for five to eight days, and subsides by lysis. Two types of spirochaete have been recovered from patients with the disease, these are known as *L. autumnalis* A and B. To distinguish between them it is necessary to resort to serological and pathogenicity reactions. The authors find that *L. autumnalis* resembles *L. icterohaemorrhagiae*. It produces a very similar disease in guinea pigs and is agglutinated, though only to a low titre, by the serum of patients suffering from Weil's disease, moreover, a serum prepared by injection of a rabbit with the A strain agglutinates *L. icterohaemorrhagiae* to about a fifth of the titre *L. autumnalis* B, on the other hand, closely resembles *L. hebdomadis*, the spirochaete that is responsible for the "seven day fever" of Japan. It is only slightly pathogenic for the guinea pig, and a serum prepared against it agglutinates *L. hebdomadis*. There is apparently no group relation between *L. autumnalis* A and *L. icterohaemorrhagiae* on the one hand, and *L. autumnalis* B and *L. hebdomadis* on the other. The authors conclude that two distinct types of spirochaete have been recovered from patients with autumn fever. Type A is closely allied to *L. icterohaemorrhagiae*, but can be distinguished from it by Pfeiffer's reaction, the other is identical with *L. hebdomadis*.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

22. Rocklinghausen's Disease of Syphilitic Origin

J. L. DE LA PORTILLA and L. DAUDEN (*La Med Ibera*, March 3rd, 1928, p. 229) record the case of a woman, aged 49, who for the previous nineteen years had presented the molluscum tumours and café au lait patches corresponding with those seen in Rocklinghausen's disease. In view of the fact that her only child had died at the age of 18 months and that she had an abortion at five months, the Wassermann and Winkler tests were performed and proved strongly positive. Under specific treatment with mercury, salvarsan, and bismuth rapid disappearance of the skin lesions and an improvement in the general condition took place.

27. Concurrent Herpes and Varicella.

J. B. SHELMIRE and B. SHELMIRE (*Arch Derm and Syph*, May 1928, p. 687), discussing the association of herpes zoster and varicella, adopt the classification into four groups: (1) herpes zoster in one patient followed by varicella in others exposed, (2) followed by varicella in the same patient but not in others exposed, (3) also in those who were exposed, and (4) varicella in one patient followed by herpes zoster in others exposed. Two cases, in a father and daughter, are reported. In the father, during the course of herpes zoster of the right fifth nerve distribution, a generalized extensive vesicular exanthem resembling varicella developed, the daughter, who had no history of exposure to chicken pox, acquired a fortnight later typical varicella with lesions of the scalp and mouth. In the father's case the herpes involved the right half of the tongue and right buccal mucous membrane, with motor paralysis of the right half of the face, infratemporal in type, while the subsequent generalized varicella-like eruption involved the glabrous skin of almost the entire body and oral mucous membrane with the exception of the scalp and those parts not already the seat of herpes. At the necropsy pathological changes were found in the right Gasserian ganglion similar to those found in the spinal root ganglion in cases of herpes of dorsal root distribution. The authors emphasize the importance of obtaining a detailed history and inquiry as to exposure in every case of zoster and varicella. It is generally accepted that the vesicle contents in herpes zoster are not virulent for rabbits, and in the case reported the results of inoculation of a scarified cornea were negative.

28. Osteo-arthritis of the Hip Following Paratyphoid Fever

J. MADIER and R. DUCROQUET (*Bull Soc de Pédi*, March 20th, 1928, p. 157) record the case of a boy, aged 5 years, who, on the fifteenth day of a febrile attack, developed arthritis of the right knee and ankle. The limb was put in plaster and the arthritis subsided but on the thirtieth day pain and swelling of the right hip developed. An x-ray examination revealed a destructive lesion of the neck of the femur. Under treatment with rest in a plaster apparatus the pain disappeared, but a skilgram taken five months after the onset showed a complete disappearance of the head of the femur. The Widal test was positive in 1 in 50 for *B. typhosus*, negative for *B. paratyphosus* A, and positive in 1 in 800 for *B. paratyphosus* B.

29. Combined Immunization against Diphtheria and Scarlet Fever

D. J. H. POT, sen (*Nederl Tijdschr v Geneesk*, March 17th, 1928, p. 1311), states that simultaneous active immunization against diphtheria and scarlet fever were first employed in 1925 by J. Parlane Kinkoch, the medical officer of health for the city of Aberdeen, who had 1,305 school children so treated, the scarlatinal toxin being injected into one arm and diphtheria toxin antitoxin into the other. No bad effects were noted. In 151 of these cases the Dick and Schick reactions were examined later, with the following results: In 80 per cent the Dick test was negative, feebly positive in 11 per cent, and distinctly positive in 9 per cent; while the Schick test was negative in 54 per cent, feebly positive in 25 per cent, and distinctly positive in 21 per cent. In the course of the eleven months following immunization six of the children developed scarlet fever and two diphtheria. Professor Aldershot of Utrecht has recently prepared a mixture of scarlet fever toxin with diphtheria toxin antitoxin, under the name of "difo," which has been employed on a large scale at The Hague Noordwijk Dordrecht and other places in Holland, with satisfactory results and little, if any, reaction.

30

Curable Typhoid Arteritis

L. RAMOND (*Presse Méd*, March 10th, 1928, p. 315) records the case of a man, aged 43, who, on the tenth day of typhoid fever, was suddenly seized with severe pain and complete loss of power in the lower limbs, which became cold and discoloured, especially at the extremities. Within twelve hours, however, considerable improvement occurred, and on the following day the appearance of the lower limbs was absolutely normal. Although the patient complained of tingling in the palmar aspect of the right hand, especially in the last three fingers, the skin was not cold or discoloured. The symptoms lasted three days and then disappeared. Subsequent recovery was uneventful. The case is considered an example of the non-obliterative parietal arteritis occurring in typhoid fever, of which instances were described by Vulpius in 1883 and later by Tholozan and Riblanc.

31

Prevention of Measles by Goat Serum

L. J. HALPERN (*Journ Amer Med Assoc*, April 7th, 1928, p. 1109) reports on 50 measles contacts who were given an antibacterial and antitoxic serum from goats which had been immunized with the diplococcus regarded by Sundeblom as the cause of measles. Five died three to ten days after inoculation, not of measles but of the disease (pneumonia or malnutrition) for which they had been admitted. Of the remaining 45, 28 (63 per cent) entirely escaped an attack, and the majority of the 17 who developed the disease had it in an attenuated form, none had any complications or any serum reaction.

32

Meningococcal Septicaemia

G. MAHIEU (*These de Paris*, 1928, No. 16), who records seven cases in patients aged from 20 to 54, states that within recent years meningococcal septicaemia appears to have become more frequent than cerebro-spinal meningitis. It was for a long time confounded with other forms of septicaemia and various skin disorders of a purpuric type, but is easily distinguished at the present day by a triad consisting of fever which is often of an intermittent type, eruptions the commonest of which resembles erythema nodosum but which may be also morbilliform or scarlatiniform, and arthralgia and myalgia. The diagnosis is often confirmed by a positive blood culture. A negative examination, however, does not contraindicate treatment by antimeningococcal serum, which should be given subcutaneously, intramuscularly, intravenously, and, if necessary, intraspinally. In refractory cases fixation abscess or shock therapy should be employed.

Surgery.

33. Phrenico-exalresis in Pulmonary Tuberculosis.

J. GRAVENSEN (*Ugeskrift for Læger*, April 12th, 1928, p. 333) has treated thirty cases of pulmonary tuberculosis at the Vejle Sanatorium in Denmark during the past four years by means of phrenico-exalresis, the principle of which—paralyzing half the diaphragm so as to limit the excursions of the base of one lung—was first advocated in 1911 by Stuerz. The author has found this operation of little value in association with an artificial pneumothorax on the same side, but he has found it beneficial as a supplement to thoracoplastic operations in certain cases. By practising phrenico-exalresis as a preliminary to a thoracoplastic operation he has been able to reduce the severity and extent of the latter operation. Such a preliminary step assures a more gradual collapse and thus minimizes the injurious effects on the other lung and the general condition. The subsequent thoracoplastic operation is rendered less dangerous, as the risk of an aspiration pneumonia of the lower lobe following a partial thoracoplasty of the upper part of the chest is reduced. Phrenico-exalresis was performed in ten cases without any supplementary operation in the remaining twenty cases it was employed in conjunction with some other form of collapse treatment, which consisted of artificial pneumothorax in three cases and thoracoplastic operations in seventeen. At first sceptical, the author has come to regard phrenico-exalresis as a useful supplement to thoracoplasty in certain carefully selected cases, but he insists that a statistical advocacy of this procedure would be useless so far as his own material is concerned, both because of its smallness and of its lack of uniformity. He adds that the operation is so easy technically, and causes the patient so

little discomfort, that it may well be attempted in suitable cases. It is, however, useful rather as a supplement to other methods of treatment, general, specific, and operative, than as a totally independent measure.

34 Naevus Carcinoma and Melano sarcoma.

K VOLKMANN (*Zentralbl f Chir*, May 26th, 1928, p 1299) records the case of a married woman who had had for eighteen months a reddish spot in the upper part of the right breast, apparently a naevus. In less than a year a small wart appeared which grew to the size of a penny. It was chafed by the clothing, but was otherwise painless. The wart was excised and the skin was sutured. Six months later an axillary tumour appeared, which was not diminished by inunction. In the upper and outer quadrant of the right breast there was a painless well healed half inch scar, the breast appeared otherwise normal. In the axilla there was a painless tumour larger than a walnut, when excised the macroscopic appearance was very suspicious, and some hard cords could be felt running towards the breast. The tumour consisted of a group of enlarged lymph glands, embedded in fat. On section the appearance was that of medullary cancer with old and recent haemorrhages and infarcts. Histologically, the lymphoid tissue was replaced by neoplastic tissue, and apparently it was a non-pigmented naevus carcinoma. The patient died a few weeks later from melano-sarcoma. Volkmann observes that similar apparently non-malignant tumours are excised so frequently by general practitioners that it is seldom considered necessary to obtain a pathological report. This case shows that all such tumours should be examined histologically, since an early recognition of the malignancy of a tumour, followed by prompt radical treatment, may save a patient's life.

35 Electro-cardiography and Surgical Operation.

W WACHSMUTH and G EISMAYER (*Deut Zeit f Chir*, May, 1928, p 145), in the course of a large series of operations on the head, thorax, and abdomen of dogs and human subjects, studied the action of the heart in the various stages of the operation by means of the electro-cardiograph. The changes observed, such as disturbance of conduction and automatism of subordinate centres, were found to be exclusively due to the anaesthetic and had nothing to do with the actual operation. No practical value, therefore, could be assigned to electro-cardiography during an operation, and the authors maintain that the old clinical methods, such as observation of the pulse and blood pressure, are sufficient to prevent accidents. They prefer anaesthesia by inhalation of ether, owing to its slight tendency to affect the heart. Administration of cardiac tonics such as camphor and caffeine before operation in patients with normal hearts is unnecessary, while a similar employment of digitalis is dangerous. The purely scientific value of electro-cardiographic tracings during an operation is considered doubtful, as there are numerous sources of error. Apart from the movements which may stimulate arrhythmia caused by the patient himself or those taking part in the operation, and apart from the disturbance of the current caused by the instruments in the field of operation, even the experienced cardiologist will have difficulty in recognizing disturbances in the heart's action in tracings made during the operation.

Therapeutics.

36 Insulin Therapy in Diseases of the Liver

C DREYFUS (*Paris Méd*, May 19th, 1928, p 456) describes a series of cases of parenchymatous disease of the liver, and discusses treatment. He finds that considerable benefit follows the administration of insulin carbohydrates in 5 unit doses with rectal injections of 4 per cent glucose serum. The increased resistance of the hepatic cells thus produced may be the cause of the benefit observed, and Nitzesku and Dobreff have stated that insulin is a remarkable chologogue. On the other hand, Motter has called attention to the good effects of insulin in progressive wasting, which is one of the principal symptoms of hepatic insufficiency. Dreyfus suggests that the combined treatment with insulin and carbohydrates affords a means of therapy in those cases where snob has been absent in the past. He gives details of cases of cirrhosis with enlarged spleen and simple jaundice treated successfully in this way.

37 Oral Administration of Pollen in Asthma.

J H BLACK (*Journ Lab and Clin Med*, May, 1928, p 703) compares the results obtained by oral and by hypodermic pollen therapy, and concludes that oral treatment has certain definite advantages, though satisfactory protection is secured

less often. None of the patients receiving pollen by the mouth suffered from asthma, hay fever, or urticaria as the result of treatment. The patients, with three exceptions, suffered from sensitiveness to a grass or a ragweed, or the two combined. For hypodermic therapy he used an initial dose of 0.1 c.c. of a 1 in 10,000 solution of an extract of the pollen made with 45 per cent glycerol and 7 per cent sodium chloride. The initial dose in oral treatment was 10 drops of a 1 in 20 extract, each succeeding dose being increased by 10 drops until 60 drops were being taken at a dose. The treatment was given three times daily, so that the maximum dose was reached within forty-eight hours. The extract was taken in a glassful of water, milk, or other beverage, usually before meals but not invariably. Black states that the oral administration can be employed during the season of infection, no prolonged pre-seasonal treatment being required, it can also be conducted at home. Systemic reactions do not occur, and the pain of injection is avoided. A disadvantage is that the pollen in the amount usually required is expensive, thus negating its employment in many cases of asthma. It has, however, been used with advantage as a preliminary to hypodermic treatment. The pollen of timothy grass and ragweed, being relatively inexpensive, are said to lend themselves well to this form of therapy. The percentage of complete failures is higher than in hypodermic treatment, and the author suggests that some method is required to determine in advance whether the patient is likely to respond to it.

38 Liver Treatment of Pernicious Anaemia.

G R MINOT, L J COHN, W P MURPHY, and H A LAWSON (*Amer Journ Med Sci*, May, 1928, p 539) report the treatment of more than 160 cases of pernicious anaemia by the daily feeding with adequate amounts of potent liver extract, which, it is claimed, acted specifically and simplified the treatment. In 9 to 18 grams of the standardized extract which they used there was an equivalent of 300 to 600 grams of liver. The patient was given an adequate well balanced diet containing no liver or kidney, and it is stated that the striking and rapid symptomatic improvement was comparable with that reported for cases treated with whole liver. The authors believe that the active principle in liver appears to stimulate particularly the formation of red blood cells, haemoglobin increased rather more slowly. Importance is attached to the concurrent employment of a diet rich in sources of iron and of foods which accelerate haemoglobin regeneration. It is emphasized that the continued ingestion of some source of the active principle effective in pernicious anaemia is necessary to prevent relapse.

39 E H MASON (*Journ Amer Med Assoc*, May 12th, 1928, p 1527) alludes to recent work on the dietetic treatment of pernicious anaemia, and reports a case in which the patient was kept for approximately four years on a diet containing a daily amount of 150 to 200 grams of liver. There has been no recurrence, and considerable improvement in concurrent lesions of the spinal cord has been observed. Shortly after admission to hospital the red cells numbered 880,000 per c.c. mm and the white cells 2,200, the haemoglobin was 20 per cent, and marked polikocytosis and anisocytosis were present. Nine weeks after the commencement of liver feeding the red cell count rose to 4,200,000 per c.c. mm, the haemoglobin to 79 per cent, and the leucopenia had disappeared. At the present time the blood shows 4,600,000 erythrocytes and 5,000 leucocytes per c.c. mm, haemoglobin 87 per cent, colour index 0.95, and moderate anisocytosis, but no polikocytosis, polychromatophilia, punctate basophils, or nucleated red cells. The improvement in the cord changes was marked. When the liver treatment was started the "position sense" of the toes was lost and the "vibration sense" was diminished in the right leg and absent in the left one, knee and ankle jerks were absent, with bilateral plantar extension. When walking the left foot dragged, and there was slight rombergism when standing. At the time of reporting this case practically all the subjective symptoms had disappeared, although the patient was conscious of weakness in the left leg. Objectively, the deep reflexes have returned, but a slight bilateral extension still persisted. There is considerable improvement in the vibration sense in the right leg, the gait has greatly improved, but there is still slight rombergism on standing. Achlorhydria has persisted unchanged throughout the disease.

40 Malarial Treatment of Cerebro-spinal Syphilis

C A PORTEOUS and E C MENZIES (*Canadian Med Assoc Journ*, May, 1928, p 536) describe in detail their method of treating cerebro-spinal syphilis by malarial inoculation and a trypanamide. Malarial blood is injected intravenously in a dose of 2 c.c. clotting being obtained by adding 0.2 per cent of sodium citrate, occasionally, also, a subcutaneous injection

of 3 oom of blood is given. During the febrile stage the urine is examined on alternate days, and slight albuminuria has been found in about half the cases. The tendency of nurses to sponge the patients during the pyrexial period has to be carefully checked, such sponging is not allowed until the temperature is definitely falling. Headache may be greatly relieved, or even cured, by an icebag, phenacetin or aspirin is never given, since it interferes seriously with the fever. Stimulants have not been found necessary, but a tonic containing iron is often administered during the fever, and invariably when the high temperature ceases. Patients are encouraged to drink fluid freely, and nourishing solids are given if they are desired. Should a sedative be required, hyoscin or paraldehyde does not appear to lower the fever materially, but they have seldom been found necessary. After eight to twelve chills, depending upon the condition of the patient, the fever is ended by giving 10 grains of quinine hydrochloride by the mouth in capsules three times a day for two days, followed by 5 grain doses three times a day for five days. In some cases intravenous injections of $\frac{1}{2}$ grain of quinine urea hydrochloride are given instead at daily intervals for three or four days. It has been found quite easy to stop the malaria, and there has never been a recurrence of the fever. In nearly every case a series of ten to fifteen doses of tryparsamide is given with the quinine, and a course of bisulphite is usually administered simultaneously, these courses are usually repeated within two or three months. Salvarsan and mercury are not given. In two parotic cases where the tabetic signs other than crises persist the spine is treated with galvanism and diathermy. Malarial inoculations have been employed in the presence of mild heart lesions and slight albuminuria without ill effects. The authors report that malarial treatment has greatly decreased the death rate of cerebral spinal syphilis and has produced many gratifying remissions, patients of the oxipansiv grandiose type in about the fifth decade of life responding most readily to the treatment. Optic atrophy occurred in the malarial series much less frequently than when tryparsamide was given alone.

Neurology and Psychology.

41

The Narcoleptics

S. A. KNIER WILSON (*Brain*, March, 1928, p. 63) considers that it is erroneous to describe any of the disorders of sleep as diseases. Narcolepsy is but a clinical manifestation of some morbid or diseased condition as yet unrecognized and includes all states of recurring diurnal sleep whatever the etiology may be. Five cases of narcolepsy, one of the larval or incomplete type, are described, in which the sleep seizures were associated with attacks of "tonelessness" in the limbs under the influence of emotional stimuli. Owing to lack of knowledge only a tentative classification of the various types of this affection can be made, and Wilson suggests the following: (1) recurring diurnal attacks of sleep, associated with attacks of "tonelessness," or without "toneless" attacks, (2) sleep attacks of prolonged duration, day and night sleeps running into each other, and continuous sleep. Cases belonging to the first subdivision are rare. Numerous cases belonging to the second subdivision have been reported, and in many an association with a definite pathological state such as encephalitis syphilitica or hysteria has been established, though there was no affinity between the narcolepsy and any one specific invariable disease. Prolonged sleep seizures of the second group occur under equally variable pathological circumstances. As many narcoleptics present only the appearance of sleep, but are in reality aware of their surroundings though unable to move or speak it is doubtful if narcoleptic sleep can be compared in all respects with normal sleep, it is possibly merely a syndrome linked with other psycho-pathological conditions. The "toneless" attack combines diminution or loss of volitional power and of muscle tone, consciousness is fully conserved during its course, and its exciting cause apparently resides in a stimulus of the emotional series. From a consideration of the transitions and substitutions of the two types, Wilson believes that some inhibitory mechanism is responsible for the "sleeping" and "falling," and discusses the relations between narcolepsy and other clinical syndromes, such as myoplegia, catalepsy, epilepsy, and Oppenheim's "Landschlag." The causal factors of narcolepsy are provisionally arranged as follows: traumatic, psycho-pathological, endocrine, epileptic, toxic infective, circulatory, pressure and unknown. In discussing the pathogenesis and pathology of this condition, the author states the general view that physiological centres related to the floor of the third ventricle and the region of the lter Sylvii are connected with the process of sleep, and deduces from the evidence derived from epidemic encephalitis that lesions in the vicinity of the

third ventricle are responsible for the disorders of sleep occurring in that disease. Wilson states that the many analogies between narcolepsy and epilepsy indicate a more or less similar physiological basis for each, and that various idiopathic phenomena exhibit close affinities to those of both catalepsy and epilepsy, he suggests that greater significance, from the point of etiology and of pathogenesis, attaches to the tonoloss, powerloss, motionloss awareness of numerous cases, both in the "sleep" and cataleptic attacks, than to actual sleep.

42. The Abdominal Reflexes in Epidemic Encephalitis

A. PAKODY (*Deut. Zeit. f. Nervenheilk.*, May, 1928, p. 309) examined the abdominal reflexes in 15 acute and 56 chronic cases of epidemic encephalitis whose ages ranged from 15 to 52 years. Most of the patients were aged from 15 to 30, only 8 being over 40. The reflexes were explored with a needle, which the author regarded as a more reliable method than the use of the finger or the handle of a reflex hammer. The results were as follows. Among the 15 acute cases the reflexes were normal in only 5, and weak or absent in all the rest. Relatively much fewer abnormalities of the reflexes were observed in the chronic cases. In 36 they were completely normal, in 10 they were exaggerated, and in 5 they were singular. Partial or complete absence of the reflexes was present in 6 cases. The site of the lesion causing the anomalies of the reflexes varied although it could not be exactly determined. As none of the patients showed peripheral sensory disturbance, paralysis of the abdominal muscles, or absence of tendon reflexes, the lesion was probably due to damage of the supraspinal reflex tract. In many of the acute cases, but by no means in all, the absence of abdominal reflexes was accompanied by symptoms of damage to the pyramidal tract, such as exaggeration of the tendon reflexes, ankle clonus, and transient or persistent Babinski or Oppenheim signs. The same symptoms, however, were found without any anomalies of the abdominal reflexes. Many of the chronic patients showed an absence of the cremaster reflex on one or both sides associated with the absence of the abdominal reflexes. The knowledge of the anomalies of the abdominal reflexes is of diagnostic importance. In one acute case the absence of the reflexes might have led to it being mistaken for disseminated sclerosis. A diagnosis, however, was made of epidemic encephalitis, and subsequently proved correct.

Obstetrics and Gynaecology.

43. Placenta Praevia in Exophthalmic Goitre.

D. DEUTSCHMAN (*Med. Journ. and Record*, May 16th, 1928, p. 555) believes that sufficient clinical data have been reported to support the opinion that mildly affected thyroid glands may become activated during pregnancy and may give rise to serious complications during labour, the most interesting of the latter being placenta praevia, he fully reports a case in illustration. The patient at the age of 20 had suffered from paroxysmal attacks of hiccup associated with choking sensations, which were attributed to a thyroid goitre. The symptoms subsided after tying the thyroid, but, contrary to advice, the patient married. In three succeeding pregnancies attacks of acute thyrotoxicosis developed, and in each pregnancy placenta praevia was present, the uterus itself being fibrotic. The author remarks that treatment, while not basically differing from that of an uncomplicated thyroid condition, should eliminate all strain on the damaged cardiovascular system. Four important procedures are the control of haemorrhage, the termination of pregnancy, either by Caesarean section or per vaginam according to the case, the production and insurance of haemostasis and the combating of the resulting anaemia. According to Dentschman, this case illustrates the following points. There exists a family predisposition, generally spoken of as a thyroid diathesis in the causation of exophthalmic goitre. Pregnancy may aggravate the condition of exophthalmic goitre by bringing on latent symptoms of an otherwise quiescent syndrome. This is probably caused by toxic hormones disturbing the physiological balance or normal equilibrium existing between the pituitary body, the ovary and a previously affected thyroid gland. The pathological condition of the latter appears to be an etiological factor of placenta praevia. This is probably brought about by ovarian hormones, which predispose to the formation of a few uterine fibroids, and these in turn prevent a normal decidua reaction with subsequent abnormal implantation of the fertilized ovum. He adds that, despite the frequently reported favourable results a patient suffering from toxic adenoma with hyperthyroidism or from exophthalmic goitre, should not be permitted to continue pregnancy, lest her life be jeopardized by complications during labour.

44. Torsion of the Fallopian Tube.

A MANDELSTAMM (*Zentralb. f. Gynak.*, April 21st, 1923, p. 1009) records two cases illustrating the diagnostic difficulties which may be caused by torsion of the Fallopian tube. In the first case a 2 para, aged 26, suffered after seven weeks' amenorrhoea from abdominal pain and vaginal bleeding. Puncture of the pouch of Douglas, which contained an elastic tumour, gave issue to dark blood with small clots. Operation showed the tumour to be the left tube, rotated through 360 degrees, it contained blood, and chorionic villi were found microscopically. The peritoneal cavity was free from blood. It was doubtful whether the abortion preceded or followed the rotation. The second patient, a 5 para, aged 35, suffered from pain and pyrexia ten days after an attempted induction of abortion following six weeks' amenorrhoea, an inflammatory adnexal condition was diagnosed. During the ensuing weeks pain persisted, and was accompanied by obstruction of the rectum. A tumour in the pouch of Douglas was regarded as either a retrocervical myoma or a retrouterine haematocoele from ectopic pregnancy. Successive punctures of the pouch of Douglas gave vent to clear fluid, blood stained fluid, and thick blood respectively. At operation (which for this reason and because the erythrocyte sedimentation was accelerated was expected to reveal an inflammatory or twisted ovarian tumour) it was found that the twisted tube contained the ovum of an uninterrupted sixteen weeks' gestation. R. SCHREINER (*ibid.*, May 5th, p. 1139) describes the case of a 2 para, aged 40, who at an interval of twelve months had two attacks, each following a sudden exertion, of acute pain in the lower abdomen, there was pyrexia and a tender tumour in the posterior fornix. After fourteen days' conservative treatment the fever disappeared, but the pain persisted. An operation revealed a right parovarian cyst, and on the left an adnexal tumour composed of a cyst, probably parovarian, and the Fallopian tube irreducibly twisted through 720 degrees.

45. Ergot Poisoning in the Puerperium.

H. L. MOSKOWITZ (*Amer. Journ. of Obstet. and Gynecol.*, April, 1923, p. 549) alludes to three cases of ergot poisoning following self administration of ergot for the induction of abortion. As evidence that certain patients evince idiosyncrasy for the drug, he states that one drachm of the fluid extract has caused morbid symptoms to appear, while ounce doses have been followed by nontoward effects. It must be remembered, however, that ergot preparations vary widely in their content of active principles. Moskowitz describes the case of a 2 para, aged 35, delivered in hospital after a thirty six hours labour, who, in consequence of puerperal pyrexia associated with foul, scanty lochia and soft, large uterine, was given 2½ ounces of fluid extract of ergot, in drachm doses three times daily, from the first to the sixth days post partum. On the sixth day she fainted and collapsed, having complained of coldness, numbness, tingling, and weakness in all the limbs. Pulsation was found to have disappeared in the radial, popliteal, and dorsalis pedis arteries of both sides. Headache, nausea, vomiting, and morbid mental symptoms followed, and on the eighth and ninth days gangrene of both feet appeared to be impending. Pulsation returned in the radial arteries on the ninth day, and in the popliteal arteries on the day after. Superficial areas of gangrene were noted on the dorsum of the left foot and toes. Pulsation of the dorsalis pedis on this side returned on the twenty seventh day, and the necrotic patches had healed seventy five days after childbirth.

Pathology.

46. The Inheritance of Tuberculosis.

C. MÖNCKEBERG, E. ONETTO, and J. VERGARA (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, March, 1923, p. 217) have investigated 22 cases with a view to obtaining evidence of the hereditary transmission of tuberculosis. They never found tubercle bacilli in the infant's blood or organs, nor in the placenta, but inoculations from the blood of the umbilical cord were positive in five cases. Inoculated guinea pigs, killed one month later, showed nothing except glandular swellings containing tubercle bacilli, but two animals killed at the end of five months exhibited typical tuberculous lesions. Only one of the mothers in this series suffered from generalized tuberculosis, in all the others the lesions, although serious, were pulmonary only. The authors conclude that a tuberculous mother may, and frequently does, infect her child with tuberculosis. The child may survive, and may develop normally, at least for one year. Infection does not necessarily occur during parturition, since in two cases Caesarean section was performed, the infection may therefore occur during pregnancy, and is not due to

placental tears and admixture of maternal and foetal blood. The fact that tuberculous lesions cannot be demonstrated in the infant appears to show that there is a pure tuberculous blood infection, which may account for the progressive emaciation described by some writers. The appearance of local tuberculous lesions may be a question of time and of the child's resistance. In any case, the present investigation is held to have shown that the theory of non inheritance of tuberculosis is untenable. Onimotto and his coadjutors have injected filter passing non acid resistant bacteria in guinea pigs, and have found typical acid fast tubercle bacilli in the progeny. The present authors inoculated an animal with foetal blood or placental extract, both containing tubercle bacilli, a month later the animal was found to have typical tubercle bacilli in the regional lymph glands and the abdomen, and the fluid or pus from these lymph glands contained tubercle bacilli. The viscera appeared to be healthy. It would seem that the occurrence of typical tuberculous lesions is only a question of time. The authors claim that their experiments confirm those of French observers, and that, although not final, they have shown the possibility and frequency of transmission of tuberculosis.

47. The Complement Fixation Test in Well's Disease.

SINCE some workers have stated that patients with Well's disease sometimes give a positive Wassermann reaction, and others that syphilitic patients sometimes give a positive fixation reaction with guinea pig liver containing *Leptospira icterohaemorrhagiae*, A. BESSMANS and P. NÉLIS (*C. R. Soc. de Biologie*, May 4th, 1923, p. 1234) decided to investigate the specificity of these reactions. They collected a number of serums from normal persons, syphilitic patients, persons suffering or convalescing from Well's disease, and from several animals which had been inoculated with cultures of the organism concerned. They used three separate antigens for the Wassermann test, and for Well's disease they employed a watery and an alcoholic extract of infected guinea pig's liver, and pure cultures of *L. icterohaemorrhagiae*, as controls they used watery and alcoholic extracts of normal guinea pig's liver, and uninoculated serum control medium. In the neutral test they used a fixed dose of complement and decreasing doses of serum. In all, thirteen serums from patients with syphilis giving a strongly positive Wassermann reaction were tested. None of these reacted with the leptospiral or the control cultures, and none with the watery extract of infected liver, one reacted with the watery extract of normal liver. Only eight were tested against the alcoholic liver extracts, six of these reacted positively, either with the infected or the normal liver extract. Serums from twelve normal persons gave negative reactions with all antigens, with the exception of two which reacted with normal and infected liver extracts. Four Well's serums were tested and yielded negative Wassermann reactions, they gave a positive reaction with the alcoholic extracts both of normal and of infected liver. With the pure leptospiral antigens three of the four reacted positively. The authors conclude that both the Wassermann test in patients with Well's disease and the icterohaemorrhagic complement fixation test in syphilitics remain specific and trustworthy. They suggest that the irregular results of previous workers were due to the use as antigens, of liver extracts, which often give non specific reactions.

48. Streptococci in Complications of Scarlet Fever.

P. NOBÉCOURT, R. MARTIN, and P. R. BIZE (*Presse Méd.*, February 11th, 1923, p. 177) record their researches into the nature of the streptococci isolated from certain suppurative complications in seven cases of scarlet fever—namely, cervical abscess, suppurative arthritis, otitis, and serum abscess. Although the streptococci were haemolytic like *Streptococcus scarlatinae*, they differed from it in the following respects: (1) most of them were not agglutinable by the corresponding serum, (2) they had no erythrogenic power—that is, they could not produce a Dick reaction, and (3) they were not affected clinically by scarlatinal antitoxin either prophylactically or therapeutically. This triple bacteriological, histological, and therapeutical argument is held to prove that the complications in question were due to secondary infection and not to the localization of *Streptococcus scarlatinae*. All the complications studied by the authors were of a suppurative character, and it is possible that other complications, such as simple adenitis, scarlatinal rheumatism with or without endocarditis and pericarditis, and possibly some cases of nephritis, are really late localizations of *Streptococcus scarlatinae*. It is added that the practical outcome of these investigations is that scarlet fever antitoxin should not be used for suppurative complications, which should be treated either by stock or autogenous streptococcal vaccines.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

42 Transient Pulmonary Congestion

J FELIX (*Wien Arch f inner Med*, May 15th, 1928, p 309) describes a condition which has attracted considerable attention during recent years—namely, a retrogressive obroulo pneumonia. Influenza has been responsible for many cases of chronic pulmonary infiltration, although a similar condition has been described by many writers under various titles—"spleno pneumonia," "massive pneumonia," "congestive pneumonia," "disquadrato pneumonia," "quiet pneumonia" (Vlechow), and "prolong pneumonia." It was definitely described by Laennec as "golatuous pneumonia." It has also been termed "pulmonary paratuberculosis," "tuberculous spleno pneumonia," and "specific retrogressive infiltration." Felix holds that the most appropriate description is "chronic transient pulmonary congestion." J Hasberg and Nonland term a similar condition "optuberculosis"; they consider that it is a definite pathological entity, found among tuberculous children, and consisting in a chronic non-specific pulmonary infiltration. In spite of the grave clinical symptoms the prognosis is usually favourable, all signs of infiltration disappearing generally after a few months. The disease develops insidiously. The patient's general condition is but slightly affected and usually there is little or no fever. The respiration is normal and cyanosis is absent, though there may be slight cough. The chest is symmetrical. On percussion the affected side (usually the right) is very dull especially over the upper lobe, but the auscultatory signs are very slight, there may be bronchial breathing, but rales are few or absent. The dullness is not due to pleural effusion, since exploratory puncture is negative. Skiagrams reveal homogeneous moderately dense shadows, usually extending over the entire lobe from the hilus to the periphery. The sputum is scanty and of glairy consistency, tubercle bacilli are never found. All the children under observation had a positive Pirquet reaction and some had tuberculous lesions of the skin or bones. In every case the spleen was enlarged. For several months the physical signs remained unchanged and then they disappeared gradually. Skiagrams showed that the infiltration cleared from the periphery and only an increased hilus shadow remained, this was probably due to enlargement of the bronchial and parabrachial glands. Finally, in the majority of cases, the physical and radiological signs disappeared entirely. Felix records five cases in adults whose ages ranged from 20 to 38, two had slight haemoptysis. One woman, aged 38 eventually developed chronic fibrotic pulmonary tuberculosis, another woman, aged 21 had slight haemoptysis, and subsequently developed tuberculosis, and a woman, aged 22, had all the symptoms described for two months and then recovered completely. A man, aged 24, of phthisical appearance, had a slight haemoptysis at the onset and the physical and radiological signs described previously, persisting for five months, at the end of seven months all infiltration had disappeared. In the remaining patient, a man aged 20, the physical signs on admission were suggestive of early pneumonia, but the urinary chlorides were normal. On aspiration no pleural effusion was found. The cough persisted for three or four months, and the physical signs were as described. The left upper lobe was very dull, there was bronchial breathing but there were no rales. The hilus shadows were enlarged on both sides. After four months there was no change in the physical signs, the patient was lost sight of. The author concludes that the differential diagnosis is of great importance. Influenza broncho pneumonia may be recognized by the sudden onset, thickly coated tongue, fever, and a high leucocyte count.

50 Asthma, Adrenaline, and the Blood Pressure

W KREMER (*Nederl Tijdschr v Genees*, April 14th, 1928, p 1795) as the result of observing nineteen cases of asthma in patients aged from 16 to 72 comes to the following conclusions. Injections of adrenaline, even when given daily for a long period do not raise the blood pressure, but are often accompanied by a fall in pressure as was illustrated by four of his patients. It is possible that in these cases the fall of blood pressure was caused by living in an allergen free chamber and regulation of the diet. Asthmatic patients do best with a low blood pressure, while a deterioration of their condition is associated with high blood pressure. Sometimes a rise of blood pressure is followed by an asthmatic attack and sometimes a fall of pressure is followed by improvement.

51 The Significance of Carabelli's Tubercle

J M P URDAPILLETA (*Arch med, cir y esp*, March 10th, 1928, p 337) has made a study of patients showing Carabelli's tubercle, which is a more or less well developed protuberance on the inner aspect of the upper second molar on one or both sides. It is the rudiment of a supplementary cusp, and, according to Sabouraud, its isolated presence justifies the diagnosis of inherited syphilis (see *Epitome*, 1926, vol 1, para 182). This view has met with much opposition, especially from Cubanne, who maintains that the tubercle is frequent, being found in 40 to 60 per cent of all persons, and possesses a well marked hereditary character, as he had always been able to find it in the descendants, descendants, and collaterals. Urdapilleta records sixteen cases, in ten of which Carabelli's tubercle was present, while the Wassermann reaction was negative, whereas the remaining cases, in which the Wassermann reaction was positive or there was undoubted clinical evidence of syphilis, did not present Carabelli's tubercle. Most of the patients showed disturbances of development and of the endocrine glands. Urdapilleta comes to the conclusion that Carabelli's tubercle does not possess the importance attributed to it by Sabouraud, and that it is merely an atavistic feature or a sign of mal development.

52 Hypersensitiveness in Five Generations

A E SMITH (*Arch Intern Med*, April 15th, 1928, p 472) records his observations on a family of 94 persons and five generations with regard to allergic manifestations such as asthma, hay fever, vasomotor rhinitis, urticaria, angio-neurotic oedema, and eczema. No fewer than 56.2 per cent were found to be allergic, as compared with only one in a family of 23 controls. Smith concludes that these results support the contention that allergy is familial in distribution and that special allergic manifestations are found to be prevalent among closely related persons.

53 Acute Tuberculous Pericarditis

M L BLATT and J GREENGARD (*Amer Journ Dis Child*, April, 1928, p 631) report a case of acute pericarditis in a boy, aged 9, whose the pericardial fluid gave positive reactions for tuberculosis on inoculation into guinea pigs, though there was no other evidence of tuberculous infection. The condition improved with weekly pericardial tapplings of 100 to 850 c cm for three months, 5,130 c cm being withdrawn in those punctures. The boy was discharged two months after the last tapping with an enlarged heart and diminished heart sounds, but no murmurs or friction rubs. He died in a sanatorium ten months later with generalized tuberculosis. At the necropsy evidence was obtained that prior to the pericarditis the boy apparently had a tracheo bronchial tuberculosis, unrecognizable clinically.

Surgery.

54 Periosteal Transplants in Delayed Union

H E MOCK (*Surg, Gynecol. and Obstet*, May, 1928, p 641) advocates periosteal transplants in the repair of delayed union, ununited fractures, and loss of bone substance, and shows from a summary of the literature that it is the periosteum alone of all the bone layers which plays a definite part in bone regeneration. From his own observations upon the value of periosteal osteogenesis he concludes that the periosteum is necessary for the regeneration of bone, and that therefore in cases of delayed union, ununited fractures, and loss of bone substance properly adjusted periosteal transplants will result in reconstruction of the defect. It is not suggested that such transplants are always superior to osteo-periosteal transplants or to autogenous bone grafts, because there are cases in which a certain amount of cortex removed with the periosteum or an autogenous graft may be superior to a pure periosteal transplant. In the cases reported, however periosteal transplants entirely free from any cortical substance resulted in union where this was delayed and in the repair of ununited fractures and in bridging over large bony defects, in each case the new bone formation was shown by x-ray examination to have started and continued from the transplanted periosteum. The best results were obtained the more completely the shaft at the site of the fracture was covered by the transplant. Its aim being to replace as far as possible the osteogenetic layer of

the periosteum of which the fragments have been doubled. Mock considers external splinting in alignment to be better than any method of internal fixation by means of plates, etc., and that where it is necessary to bridge over a considerable bony defect the osseous periosteal transplant is probably superior to a pure periosteal transplant, though, whatever method is adopted, more rapid and better results will follow if the shaft at the site of the defect is surrounded by a large piece of periosteum.

55 Poisoning following the Use of Hexamine and Salicylic Acid.

H EDELMANN (*Zentralbl. f. Chir.*, May 19th, 1928, p. 1230) reports an instance of poisoning following the use of hexamine and salicylic acid in a case of anuria following a surgical operation. Each ampoule of the preparation used contained 2 grams of hexamine, 0.8 gram of sodium salicylate, and 0.2 gram of caffeine sodium salicylate. The patient was a boy, aged 7, who had undergone operation for bilateral inguinal hernia. On the fourth day after operation he was making good progress and passed urine without difficulty, but subsequently anuria occurred suddenly, with restlessness, vomiting, and a rise of temperature to 103.4° F. The operation wounds appeared to be healing well. The anuria persisted for three days, when diuresis occurred. In the hope that a preparation of hexamine would increase diuresis, half an ampoule was injected intravenously. The child collapsed immediately, profuse sweating, cardiac arrhythmia, and severe rapidly increasing dyspnea ensued, and terminated fatally in fifteen minutes. Edelmann remarks that hitherto such a dose of hexamine had not been regarded as excessive in the case of a child aged 7. Our author has recommended a dose of this size for infants, and another reports having given a larger one to a child aged 3. The author suggests, however, that possibly in the present case the patient's renal disturbance and consequent non-elimination of toxic substances induced severe symptoms of fatal salicylic acid poisoning.

56. Arachnodactyly

H U KALLIUS (*Deut. Zeit. f. Chir.*, May, 1928, p. 256), who records an illustrative case, states that hitherto only twenty-four cases have been recorded of the condition to which Achard gave the name of "arachnodactyly" in 1902, after Marfan had described it under the name of "dolichostenomelia" in 1896. The condition consists in a spider-leg-like prolongation of the extremities in their distinct segments, particularly the fingers and toes, accompanied by other malformations, especially the triad of macrophthalmos, enlargement of the lobe of the ear, and hypoplasia or aplasia of the adipose tissue. Other malformations may also be present, such as congenital valvular defects, an abnormally wide foramen ovale, auricular asymmetry, deformation of the thorax, macroglossia, abnormal length of the intestine, and precocious development of the sexual organs. Kallius is inclined to attribute the condition to an intrauterine disturbance of the correlation of the glands determining growth, and particularly a disordered function of the hypophysis.

Therapeutics.

57 Dietetic Treatment of Chronic Ulcerative Colitis.

J W LARIMORE (*Journ. Amer. Med. Assoc.*, March 17th, 1928, p. 841) reports five cases of chronic ulcerative colitis, which were considerably benefited by the administration of a diet rich in vitamins. All the cases showed a definite healing reaction in the rectal mucous membrane as revealed by proctoscopic observation, and radiological investigation indicated progressive improvement. The earlier the treatment was started the quicker and the more pronounced was the benefit. Tomato juice and cod liver oil were found particularly useful, and other vitamin-containing foods employed were lettuce and peaches. The author discusses the etiological problems raised by these observations, and suggests that the usual practice of limiting the diet in this condition, thereby causing vitamin deficiency, militates against the cure of the ulceration.

58 Sulfarsenol as a Preventive of Puerperal Infection

P DELMAS and BREMOND (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, April, 1928, p. 433) advocate the use of sulfarsenol in the prophylaxis of puerperal infection, this treatment, first instituted by Riviere, has been systematically employed at the Montpellier Maternity Hospital since the end of last year in all accouchements when there was doubt as to sepsis. The drug is injected into the subcutaneous cellular tissues of the external surface of the thigh in doses of 12 cc (about 1½ grains). At first one injection was given on the day

of the confinement only. In a second series of cases the injections were administered on each of the four days following labour. No better results were obtained by the latter method, and it need only be employed in the cases most exposed to infection. A summary of the results obtained in 67 cases is given, no death occurred, and all the patients benefited from the treatment. In some, pain and swelling appeared round the point of injection, but these were infrequent and of no gravity, and in only one case were there toxic manifestations. These symptoms lasted about forty-eight hours, and were noted chiefly in non-albuminuric cases, the injections were well tolerated by the albuminuric patients.

59 The Treatment of Coll Bacilluria.

BLIEVING that coll bacilluria is a general infectious malady, G LUXS (*Bull. et Mem. Soc. Chir. de Paris*, May 18th, 1928, p. 401) maintains that treatment, in order to be efficacious, must have a triple application—namely, intestinal, bacilic, and genito-urinary. The principal one of these is the first-named, and a careful examination should be made, therefore, for underlying intestinal conditions. Lesions such as colitis and enteritis must be treated, and a strict dietetic regime is often beneficial. Constipation must be combated, the chief drugs for this purpose being paraffin oil or castor oil, holanthiasis should be looked for and appropriately treated. Diseases of the liver and gall bladder require medical or surgical attention, while hepatic, pancreatic or intestinal deficiency often yields to adequate caloric therapy. Intestinal malformations and adhesions call for the surgical intervention indicated by radiocopic examination. Finally, all infective foci, either endogenous or exogenous, such as lesions of the mouth, rhino-pharynx, tonsils, and teeth should be strictly attended to. Haemolysis treatment entails the use of vacuolus. Luxs remarks that autogenous vacuolus, being much more efficacious than stock ones, should be employed, and any of the following will prove beneficial bacterial suspensions in physiological saline, the coll soda vaccine of Mauté, the bacillon vaccine of Gaehlinger and Bécart, and the bacteriophage of d'Horelle. Genito-urinary treatment should be both general and local. General measures comprise rest and suitable diet, the taking of abundant watery fluids, urinary asepsis by means of methylene blue combined with euphoric acid or urotropine, and urine acidification. Local treatment varies with each case, and a close examination should be made to ascertain the presence of lesions in the urinary organs. Conditions that may be present and need appropriate attention are pyonephrosis or hydronephrosis, pyelonephritis, cystitis, prostatitis, spermato-cystitis, epididymitis, urethritis, strictures of the ureter, and calculi in the various organs. Luxs insists on the need of early treatment, since complete cure is much more likely when treatment is commenced on the appearance of the first symptoms.

60 Tryparsamide in Neurosyphilis.

W T LORENZ (*Journ. Amer. Med. Assoc.*, April 21st, 1928, p. 1235) reviews the treatment of 317 patients with tryparsamide and mercury. Of these, 152 were noted as having recovered completely after the time of treatment (1920-21), 4 of these have since died and 14 have returned for hospital care. Thus 134 patients have remained permanently restored to physical health and mental efficiency for periods of from five to six years—87 per cent of satisfactory results. Many other patients in this series, although far from cured, are reported to be well enough for discharge from an institution or were more fitted than previously for active life, thus affording further evidence of the therapeutic efficacy of the tryparsamide method of antiluetic treatment. It is stated that the younger the patient is at the time of treatment and the less prolonged the duration of syphilitic infection the better is the prognosis, moreover, those cases which present the grosser mental aberrations run, in many cases, a more favorable course under treatment. Although serologically and neurologically there is no definite guide to prognosis, yet alteration of the gold curve from the parietic to the meningovascular type occurs early in certain cases and is of favorable import, as also is a strong Wassermann reaction in the spinal fluid. Increase in the body weight occurs in favorable cases. Lorenz considers 3 grams a good routine dose, but individual cases require considerable variation within the range of 1 to 5 grams. The same applies to the intervals between the doses, suitable periods being once a week, twice a week, or once in two or three weeks in different cases. Eye complications, age, body weight, and serological tests help to decide the degree of treatment in particular cases. The therapeutic total dosage has been found to vary from 48 to 1,500 grams, and the duration of time under treatment from six months to two years. Very little irritation is caused by the drug, 160 grams having been injected into the same vein during four months. Lorenz concludes that in view of these latter results it can hardly be

doubted that this treatment offers a convenient and efficient therapeutic measure in neuro-syphilis, and that clinical and serological criteria without therapeutic experiment will not give information as to the efficacy or otherwise of this treatment in any one particular case. He insists that each case must be dealt with on its own merits.

Laryngology and Otology.

61. Correction of Depressed Nasal Bridge.

J. N. ROY (*Arch. Internat. de Laryngol.*, February, 1928, p. 166) reviews the different agents, such as metals, ivory, and collinoid, which have been used in rhinoplasty. He has no doubt that the method of using a graft of cartilage is the one of choice, and, in his opinion, the first floating rib is the most satisfactory site from which to obtain the graft. This rib is particularly accessible, and the removal from it of a piece of cartilage causes the patient very little pain or discomfort afterwards. The technique of the operation is as follows. After injection of novocain and adrenaline an incision is made through the mucous membrane on the left side on the lower margin of the cartilaginous septum, and a tract is prepared for the graft. Care is taken to prepare a socket close to the tip. The patient is then anaesthetized and a portion of cartilage is removed from the first floating rib, this graft is carefully shaped and placed under the skin of the bridge. All blood is removed and the incision closed with silk. The nose is lightly and carefully packed and the whole face bandaged. These dressings are retained for seven days and then removed. The patient, as a rule, leaves the hospital on the sixteenth day.

62. Peritonsillar Infection

S. D. GREENFIELD (*Arch. of Otolaryngol.*, March, 1928, p. 239) relates his personal experience of about 190 cases of peritonsillar infection. He thinks that the anatomy of the tonsil and its bed predisposes to the collection of inflammatory products between the tonsil and the neighbouring structures. In the majority of cases the pus collects in the supratonsillar fossa and provides the outstanding feature of bulging and swelling of the soft palate, with an *oedematous uvula*. In two other types of case the pus collects between the tonsil and the posterior pillar, with forward displacement of the tonsil, and between the tonsil and the superior constrictor. Difficulty in opening the mouth is most marked in this latter type of case, whereas dysphagia is most marked when the pus accumulates behind the tonsil. Pus may pierce the superior constrictor and collect in the pharyngo-maxillary space; the great vessels may be implicated. Pus may gather round a carious last upper molar and simulate peritonsillar abscess. Recurring peritonsillar abscess may be multiple or multiloculated on account of the formation of fibrous partitions. There is also the latent abscess, which is only discovered as a collection of pus during tonsillectomy. Bilateral peritonsillitis is otherwise typical, but tends to occur after very acute tonsillitis. The differential diagnosis is from retropharyngeal abscess, especially in children, from diphtheria, especially the septo type, and from sarcoma of the tonsil, especially before it has reached the ulcerated stage. The complications of peritonsillar abscess may be very dangerous and include general sepsis, which, unexpectedly, is comparatively rare. It is more likely to occur in those cases where the superior constrictor is pierced. In one of the author's cases this condition progressed to a fatal meningitis. In the same group of cases the vessels in the pharyngo-maxillary fossa may be involved and give rise to very violent haemorrhage. The author has had one case of acute oedema of the larynx in a patient whose abscess cavity he packed with gauze. Other complications are cervical gland abscess, polyarthritides, and acute endocarditis. As to treatment, the author urges, most strongly, early and adequate incision.

63. Perforation of the Pituitary Fossa.

F. A. PICKWORTH (*Journal of Laryngol. and Otol.*, March, 1928, p. 186) describes the *post mortem* findings of a case of epilepsy and insanity associated with a perforation of the pituitary fossa by a septo lesion of the sphenoidal sinus. The patient had suffered from fits for four years, and recently from delusional insanity. Suppurative parotitis occurred just before death. At the necropsy, scoliosis, cardio-vascular degeneration, and broncho-pneumonia were found, there was also a lesion of the right sphenoidal sinus, pituitary fossa, and adnexa which consisted of a depression in the diaphragma sellae, anterior to the stalk of the pituitary. This gland was surrounded by a thickened and somewhat ragged capsule, which was not adherent to the floor of the fossa, as is generally the case but was separated from it by a quantity of grey mucinous fluid in the posterior part, while anteriorly

it was attached to a thickened bony ridge. The mucinous fluid was seen to be draining away through a hole 2 by 1½ mm, this communicated with the right sphenoidal sinus, which also contained similar fluid. Histological and bacteriological examination of the mucinous material revealed no definite organisms, but histological examination of the pituitary gland showed a large number of granule cells in the anterior portion, which also contained masses of colloid. There were areas of small but not very recent haemorrhages in the capsule. Near the larger masses of colloid, and more sparsely in other parts of the capsule, were numbers of bodies resembling organisms which apparently filled the minute lymphatic vessels or cerebro-spinal fluid spaces. They were smaller than the usual cocci, but the author has no doubt that they were attenuated diplococci of an originally virulent type, which had been strongly inhibited by the patient's natural defences. Pickworth considers that the value of this case lies in the fact that the macroscopic bone lesion draws attention to the method by which micro-organisms invade the central nervous system. Careful investigation shows that an identical process can occur without such macroscopic lesion, the bony walls merely acting as a sieve to chemical substances, micro-organisms and their products. Infective lesions of the sphenoidal sinus are often found in cases of mental disorder and in such diseases as encephalitis lethargica. It is probable that in cases of sinusitis micro-organisms and their toxic products penetrate the bony wall and produce disturbances of pituitary function, which in their turn give rise to mental disorder and epilepsy. In an appendix the author describes a method of staining those altered Gram negative bacteria.

Obstetrics and Gynaecology.

64. Vesico Uterine Fistula.

G. K. SIMS (*Journal Amer. Med. Assoc.*, March 10th, 1928, p. 759) describes a case of spontaneous healing of a vesico uterine fistula, and mentions the scanty reports in the literature of this apparently rather rare condition. He believes, however, that these fistulas probably occur more frequently than is suspected, a small opening being formed and healing spontaneously without the symptoms being observed. All the instances reported followed labour in three forceps had been applied, in two others pituitrin had been administered before delivery, and in the remaining six cases there was a history of prolonged labour in which the uterine contractions were unusually strong. The foetal membranes had invariably been ruptured several hours before delivery. In Sims's case inability to retain urine was observed on the fifth day after difficult delivery, following catheterization and irrigation of the bladder, water was observed to come from the vaginal vault. On instillation of methylene blue in the bladder a small stream of the solution escaped from the cervical os. Cystoscopic examination revealed an area of trauma in the region of the left ureteral orifice. After catheterization and irrigation of the bladder each morning for five consecutive days, a silver iodide preparation was instilled. On the fourteenth day after delivery the patient was discharged from the hospital with urine still trickling at intervals from the vaginal vault, ten days later this leakage ceased, and a fortnight afterwards recovery was complete.

65. Operative Treatment of Tumour of the Adnexa.

According to W. SIGWART (*Med. Welt*, April 28th, 1928, p. 637) it is unanimously agreed that in the acute stage of any inflammatory process of the ovaries or tubes conservative treatment is essential, but opinions differ as to the stage at which the condition should be considered healed. The author finds that recurrence is frequent, and believes that few complete cures result from conservative treatment. Indications for operation are as follows: long standing cases in which conservative treatment has failed and it is probable that the tumour will be reasonably easy to remove, recent cases where medical treatment has been unable to relieve the symptoms, and cases with atypical haemorrhages caused by a tubo-ovarian tumour, or with severe disabilities from the tumour and adhesions. Sigwart remarks that an operation should not be undertaken until after prolonged clinical observation, the temperature must be steady and not above normal, and any fall in the red blood count must not be abrupt. As regards the operation, many of these patients are young; it is therefore advisable to preserve the ovaries or any sound ovarian tissue, any bleeding points must be secured and all raw surfaces peritonized. No drainage is used, and the uterus is ventrally fixed to prevent retroversion by adhesions. The author has treated 546 cases, 164 by operation, there were three deaths, all from peritonitis, in old standing cases where peritonization was

difficult, there were no fatalities in the very severe cases with large pus tubes. He adds that the best results are obtained if operation is undertaken as soon as conservative treatment has been given a fair trial. The after results are best in those in whom menstrual function has been preserved, of these, five patients became pregnant subsequently.

65

Pernicious Anaemia of Pregnancy

A POHL (*Zentralbl. f. Gynäk.*, June 2nd, 1928, p. 1384) reports an only case of the pernicious anaemia of pregnancy, and remarks that these are rarely seen owing to absence of symptoms, while the uncertainty of the blood picture renders its diagnosis from a simple anaemia difficult, this is the more regrettable since treatment, to be of any use, must be commenced early. Pohl's patient was admitted to hospital at the third month of pregnancy suffering from pyelitis, the anaemia being a secondary consideration. Her haemoglobin was 50 per cent and did not improve with iron and arsenic, indeed, at the sixth month it fell to 42 per cent, the dosage was increased and the haemoglobin percentage rose but sank again. There was no oedema, jaundice, or splenic enlargement, the colour index was never over 1, there were no enucleated red cells, leucopenia, or lymphocytosis, but polychromasia and anisocytosis were present. Pregnancy was artificially terminated. During convalescence normoblasts and megalocytes appeared, but three and a half months later the blood was entirely normal. With regard to diagnosis, Pohl remarks that an anaemia getting worse in spite of treatment is suspicious, as also are oedema, enlarged spleen, urobilin in the urine, jaundice, and retinal haemorrhages. This anaemia is usually held to belong to the second half of pregnancy, but in this case, and probably in others, it began much earlier and remained stationary until the sixth month, when it grew progressively worse. The author states that marked polychromasia distinguishes the pernicious from the chlorotic anaemia of pregnancy, the other blood changes are seen in normal pregnancy and in the toxaeasias, and these may pass on to the pernicious form with its very serious prognosis. There are two factors in the etiology—namely, haemolysis, often present in pregnancy, and a poor constitution, with involvement of the bone marrow resulting from disturbance of the internal secretion, or from overwork of the marrow leading to haemorrhage, or from an infection, especially syphilis. Recurrence may follow if pregnancy occurs soon after recovery. The best treatment, according to Pohl, is termination of the pregnancy if the diagnosis is made early enough. Blood transfusion and injection have not given good results, but are useful in hastening convalescence and preventing death in the puerperium. Liver treatment has not yet been tried.

Pathology.

67

Cardiac Hormones

DURING the last few years various workers have isolated substances to which they have ascribed a hormone-like action on the heart. Thus Asher obtained from liver an extract which was at first thought to be a specific cardiac stimulant, but was subsequently found to consist of minimal quantities of bile salts. I FISHER, E. A. MÜLLER, and G. ZUELZER (*Med. Klin.*, April 13th, 1928, p. 576) have been able to show that substances free from protein and salts, and not decomposed by boiling, can be isolated from the liver, and that these produce dilatation of coronary vessels and improve the tone of such mammalian hearts as those of the cat and dog. G. ZUELZER (*ibid.*, p. 571) performed experiments with a preparation called *entoton*, obtained by special methods of extraction from the liver, whether this is related to the preparations used in the treatment of pernicious anaemia is not stated. He found that 1 to 2 day old frogs' hearts which refused to beat when irrigated with Ringer's solution contracted regularly again when one or two drops of the *entoton* solution were added, the pH of the Ringer's solution being carefully controlled meanwhile. In Starling's heart lung preparation (dog) the coronary oroluation gradually diminishes under ordinary conditions, but on the addition of *entoton* the coronaries dilated and the cardiac tone improved. Zuelzer also treated 100 cases of impaired cardiac function with intramuscular injections, and came to the general conclusion that improvement in motion and amelioration of symptoms resulted. He adds that his cases are too few to draw definite conclusions as to which type of cardiac disease is most benefited by the preparation. It was, however, found useful during convalescence from influenza pneumonia. The effect on the blood pressure seems to have been variable, in some cases of heart failure with low blood pressure a rise of 10 to 20 mm. of mercury was recorded, while in others with

a high blood pressure a fall of 30 to 40 mm. occurred. HABERLANDT (*ibid.*, p. 577), working with an extract prepared from the apex of the bullock's heart, found that in rabbits ventricular fibrillation induced by strong faradic stimulation could be abolished again by injection of a dilute solution of his preparation, the blood pressure raised by adrenalin was lowered, and in rabbits in which the blood pressure had been lowered by venesection it was raised. R. RIGLER (*ibid.*, p. 574) considers that this so-called cardiac hormone is chemically closely allied to histamine on the one hand and vitamin B on the other. He thinks that it belongs to a group of non-specific products of metabolism which have an effect on cell activity either by altering permeability or by causing a change in the distribution of ions.

68. J. MOUNON (*Presse Méd.*, May 9th, 1928, p. 582) refers to the attempts of many investigators to discover a cardiac hormone. Some observers claim that beneficial results have followed the injection of extracts of heart muscle or of nodal or neuro-muscular tissues, others have recorded similar results after the employment of extracts of liver or lung. It would appear that some of these substances are either derived from glycogen or that glycogen is necessary to their formation. Certain experiments appear to indicate that the active substance "antomatine" or "cardiac hormone" is identical with histamine, a powerful vaso-dilator found in many organs and tissues. It has also been suggested that "antomatine" is closely related to vitamin B, and that the absence of this substance may account for the grave cardiac disturbances associated with beriberi. Mounon concludes that it is premature to employ myocardial extracts or any other animal organ products in the treatment of heart disease.

69

The Cerebro-spinal Fluid in Children

D. STEWART (*Arch. of Dis. in Child.*, April, 1928, p. 95) examined fifty children with a view to defining the normal characteristics of the cerebro-spinal fluid in early life. The youngest child was 7 days old and the oldest 12 years. Twenty-eight were under the age of 2 years. The children were all healthy. Stewart found that pressure studies were only of negative value, but they proved the uselessness of manometric readings in young children, where so many disturbing factors may upset the calculations. They showed also how very inaccurate is the estimation of the fluid tension by observation of the rate of flow. The cell count was found to be normally from 20 to 30 per cmm. in infants, and to decrease gradually as the age increased, becoming identical with that of adults (3 to 7 per cmm.) at the age of 10 to 12 years. The total protein content was found to be similar to that in adults, but varied in the lumbar region, in the cisterna magna, and in the lateral ventricles. The sugar content of the fluid in children varied directly with the blood sugar. Stewart remarks that in order to assist the clinician the estimation of the sugar in the fluid should be associated with determination of the blood sugar. The chloride content seemed to vary from 630 to 760 mg. per 100 cmm.—a variation of 130 mg.

70

The Reticulocyte Response to Liver Therapy

G. R. MINOT, W. P. MURPHY, and R. P. STETSON (*Amer. Journ. Med. Sci.*, May, 1928, p. 581) discuss the response of the reticulocyte (a cell intermediate in maturity between the nucleated erythrocyte and the adult red blood corpuscle) to liver therapy in over 150 cases of pernicious anaemia. It is held that the anaemia of pernicious anaemia is primarily dependent on the failure of the primitive cells in the bone marrow to differentiate towards mature erythrocytes. In this disease the administration of large amounts of liver, kidney, or potent fractions of liver causes a prompt and pronounced but temporary increase of the reticulocytes in the peripheral blood, which is not the case in normal subjects. This response is ascribed to the specific active principle promoting the growth of the primitive cells in the bone marrow, accompanying it other immature bone marrow elements may appear in the blood, and the leucocytes and platelets increase in numbers. The percentage increase of reticulocytes is in inverse relation to the level of the red blood cells, and cases with more than three million erythrocytes per cubic millimetre never exhibit more than a slight response. In all cases treated with adequate amounts of active principle the red blood cells rapidly increase to normal while small amounts or complications of the disease may cause only a slight reticulocyte rise, which may be delayed, and a weak response may not soon be followed by a significant erythrocytic increase. A reticulocyte response to liver therapy may occur in other anaemias, but is absent or slight in ordinary cases of secondary anaemia. Some cases of anaemia in pregnancy have shown a marked response, and this has also occurred in spure

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

71. Schilder's Encephalitis

C P SIMMONS (*Brit Journ Child Dis*, April-June, 1923, p 83) states that this disease, otherwise called "encephalitis periaxialis diffusa," which was first described by Schilder in 1912 was probably unknown except to a few neurologists until the appearance of papers by Bonman and Collier and Greenfield in 1924, since when interest in the subject has been widespread and much has been added to the clinical and pathological features of the disease. Schilder's encephalitis usually occurs in children and young subjects with no tangible causal factors or antecedents. The onset is a few days, the course progressive with some remission to a fatal issue, and the duration from a few months to three years. The chief early sign is cerebral blindness, which becomes complete, and is followed by mental retardation and increasing spastic paralysis. Unsteadiness from periorbital involvement and deafness may be conspicuous. The condition is usually bilateral, but may commence on, or be confined to, one side. The disease may begin in the occipital lobes or in some other part of the brain. The optic nerves are occasionally involved. In several cases a familial incidence has been noted, which indicates an infective cause with occasional congenital infection, or suggests the notion of an inherited atrophy. Naked-eye examination shows areas of softening in the cortical white matter of the affected lobes. Histologically, there is general infiltration of the brain with round cells engaged either in the removal of myelin or the formation of glial fibres. The vessels are surrounded with fat-laden granular cells, phagocytes of glial origin, and small round cells of the size and shape of lymphocytes.

72. Transient Insulin Hypoglycaemic Hemiplegias

J M RAVID (*Amer Journ Med Sci*, June, 1923, p 756), discussing the symptoms observed by various authors in insulin hypoglycaemic reactions, states that these are indicative of some involvement though temporary, of the central or peripheral nervous system. He reports a case of diabetes in a man, aged 34, who had three different attacks of complete hemiplegia during such a reaction. The attacks were transitory, lasting from three to seven hours, were followed by complete recovery and left no sequelae of the paralysis. Arterio-sclerosis and cardio-renal disease were excluded, and in the three periods of hemiplegia a definite hypoglycaemia was demonstrated, the blood sugar ranging from 0.028 to 0.015 per cent. The hemiplegias were not commensurate with the degree of general symptoms, the entire symptom complex being comparatively mild. It was shown that this new phenomenon was not a syndrome *qui generis* but belonged to a fairly common group of transient pareses and hemiplegias, such as sometimes occur in tuberculosis, alcoholism, and uraemia. Ravid discusses the views and experimental data regarding the mechanism and nature of the action of insulin and concludes that, apart from all other effects of insulin in hypoglycaemic reactions, there is always a definite action on the central or peripheral nervous system, and that this is of a functional character, no actual anatomical lesion but only a temporary disturbance being produced. He advances the hypothesis that this action may be initiated directly by the insulin itself or by the still unknown products of carbohydrate metabolism which it originates, creating, as it were, a "vacuum" for glucose in the nerve tissues (Krogh's theory), or a process similar to this. The resulting effect may manifest itself by alteration of function of either the nerve elements themselves or the blood vessels supplying them.

73. Vincent's Angina.

V JELINEK (*Acta Otolaryngologica*, 1927, vol II, Fasc 4, p 533), who has investigated the occurrence of Vincent's angina in the Jugo-Slav army, discusses its etiology. The first theory advanced is that it is due to vitamin deficiency. It was found to occur, however, in well nourished troops on liberal and varied diet and to attack one regiment where another escaped, though the rations were similar. The second theory is that it is an infection set up by irritation of the molaris. Jelinek has observed that it usually occurs in some position other than that of proximity to the molars and he can see no connexion between the two conditions. The third theory attributes the disease to a specific infection of the Plant Vincent spirochaeta and *B fusiformis*. These organisms are consistently found in this condition, its

infectiousness is shown by the way in which it spreads through a regiment of young healthy soldiers, and by the way in which secondary infections occur, especially on the fingers. Surgeons in attendance, dentists, and other patients in the same ward all tend to be infected, but other regiments in the same garrison or division often escape entirely. Jelinek considers that the spirochaeta of Plant Vincent is the specific organism which originates the inflammation and ulceration, while the bacillus acts as a parasite and continues the ulcerative processes. The author's method of treatment consists in applying an ethyl chloride spray to the affected parts, protecting healthy tissue, and especially the teeth, with wool, iodine rubber, or, in some cases, with his own or an assistant's finger. Alternatively, and especially for ulcers of the tonsil, he sprays ethyl chloride on a piece of cotton wool, allows it to freeze, and then applies it to the ulcer. He sometimes substitutes a piece of ice for this purpose. Gargles of potassium chlorate or permanganate, and later hydrogen peroxide, are used, and after the ulcers are healed the mouth is rigorously cleaned, with the removal of tartar and carious teeth. The treatment is not at all painful, and may have to be repeated several times.

74. Influenza in Infants

L RAUCH (*Thèse de Paris*, 1923, No 95), who records thirteen illustrative cases, remarks that on exposure to infection infants are as susceptible to influenza as adults. The pandemic of influenza of 1918-19 seriously affected infants in both private families and in crèches. The mortality was particularly high among the cases with influenza laryngitis, broncho-pneumonia, encephalitis, and choleraic diarrhoea. From 1918 to 1922 the mortality ranged from 0 to 66 per cent, according to the epidemic. Influenza sometimes assumes special forms in the infant, such as those resembling whooping cough and others associated with emphysema and croup. Ever since 1918 small epidemics of influenza in infants have occurred every winter and often assume a grave form, which may be cerebral, pulmonary, or of the choleraic type. The principal features of these severe forms is a profound intoxication, which appears at the onset of the disease. The most successful treatment appears to be transfusion of blood in the toxic forms, oxygen in the pulmonary forms, and strychnine and sparteine in the adynamic forms.

Surgery.

75. Diverticulum of the Duodenum.

A J BRNGOLEA (*Bull et Mem Soc Nat de Chir*, May 26th, 1923 p 726) reports a case of a woman, aged 46, who had jaundice preceded by pain and with no pyrexia, this disappeared in two months after treatment with alkalis and cholelago. Two years previously she had been vomiting a liquid like saliva, always about 10 p.m. After two further attacks of jaundice a radiological examination showed a big stone in the gall bladder and in the duodenum a round opaque spot which disappeared after forty-eight hours. A diagnosis of gall stones with intermittent obstruction of the biliary ducts was made and the patient was operated on, the gall bladder was found to be distended and full of a white fluid, the wall being slightly thickened. Retrograde cholecystectomy was performed and the biliary ducts were found to be free, the intestines and duodenum being normal. Convalescence was without incident, but after two months jaundice recurred, and a further radiograph showed a duodenal diverticulum near the ampulla of Vater. The author considers it probable that the jaundice was due to intermittent obstruction of the bile duct by the retention of intestinal contents in the diverticulum. This condition could not be relieved except by removal of the diverticulum, which, however, was only discovered after operation by a more careful x-ray examination.

76. Treatment of Cold Abscesses

I MARIAN (*Zentralbl f Chir*, June 9th 1923, p 1420) states that during the last three years a mixture of chloroform and iodine has been used for injection at the Bucharest Clinic for infantile surgery and orthopedics. Its composition is as follows: metallic iodine 6 grams, glycerol 10 grams, chloroform 60 grams, and oil of almonds 40 grams. The dose to be injected depends upon the amount of pus evacuated and the age of the patient, 1 to 2 c.c. being the dose for

children under 5 years of age, and 8 to 10 c cm the dose for adults. The abscess is punctured after local anaesthesia with ethyl chloride, and the injection is given after complete evacuation of the contents. The evacuation and injection should be repeated at intervals ranging from every two or three to every five to seven days until the fluid is of a chocolate brown colour, when further injections are unnecessary. If too large a dose of the mixture is given at short intervals signs of iodine poisoning may occur in the form of an eruption, severe thirst with a burning sensation in the larynx, vomiting, hemilia, emaciation, cardiac palpitation, and albuminuria. On the occurrence of these symptoms the treatment should be discontinued, and only resumed after their disappearance, when smaller doses should be given.

77 Surgical Treatment of Typhoid Perforation

C BIFULCO (*Stadium*, May 20th, 1928, p 191) reports three successful cases of operation for perforation in typhoid fever. The statistics collected from the large hospitals of England and the United States show a percentage of 34.36 of deaths from perforation, while in Venice the percentage is only 15.15. He thinks there is reason to believe that the infecting organisms vary in virulence in different parts of the intestine. That cure may take place after perforation is possible, in one of the author's cases operation showed two unhealed perforations and one recently healed, but such an event must be looked upon as a surgical curiosity. Bifulco adds that the earlier the operation is performed the better it is for the patient, it is preferable in the pre-perforative stage, when peritonitis is just starting. The difficulties in the diagnosis of this early stage are fully discussed. Sgambati's urine test is not considered very reliable. The operation itself should be performed as speedily as possible, and without lavage of the peritoneal cavity.

78. The Transmissibility of Cancer

C REGAUD (*Bull de l'Acad de Méd*, June 5th, 1928, p 617) asserts that the seeming infectivity of cancer is due to its transmission by various factors and not to contagion. He recalls that the cancer rate among the medical and other attendants in general hospitals is no higher than that of the general population. Since this might be due to the excellent hygiene maintained in these institutions, and to the fact that the slow development of cancer renders impossible the denial of a previous bed infection, statistics were obtained from certain hospitals in Paris and other towns devoted to the care of women, especially those afflicted with cancer, the returns show no increase in the cancer rate among the attendant staffs and patients, despite the prolonged cohabitation of cancerous with non-cancerous individuals and the absence of all prophylactic precautions. Moreover, no greater frequency of the cancerous degeneration of old conditions, such as lupus and burns, was noted. Discussing cancer in rats Regaud lays stress on the heredity factor, and refers to the work of Maud Slye, which proves that the disease is more frequent only in the progeny of cancerous animals and in repeatedly cross bred stock. Other experimenters have reported that malignant growths can be produced in rats by the larvae of certain worms that infest the cockroach and the intestines of cats. Regaud maintains that only the cancerous agent is transmissible and not the neoplasm itself, that many etiological factors—familial and racial heredity, irritating agents used in work, the habitual use of tobacco and alcohol, and various infections, such as syphilis—account for the occurrence of cancer in various groups of individuals, and that there is not the slightest evidence, in human beings or animals, of the contagiousness of this malady.

Therapeutics.

79. Treatment of Cholera by Acid and Cresol.

F J PALMER (*Indian Med Gaz*, May, 1928, p 259) refers to a previous paper (*ibid*, April, 1925) in which the treatment of cholera with sulphuric acid and cresol is fully described, though only a few cases had then been treated, the results were such that the method has been continued during the cholera seasons of the past three years, the only change being a gradual and cautious increase in the acid dosage. The dose now employed is for patients from 1 to 3 years old cresol 1 min., sulphuric acid 3 min. aromatic water 1 oz., this ranges up to cresol 4 to 5 min., acid 10 to 15 min., water 4 oz., for patients of 12 years and upwards. The higher dosage according to age and size is secured by increasing the amount taken in proportion to the bowel area and not the strength of the cresol. The quality of the cresol is said to be of importance the preparation should make a perfect emulsion and those forming thin watery, very slightly milky

fluids should not be used internally. In severe cases the doses should be given at least every half hour for six or eight doses, and thereafter every hour for twenty four hours, being continued at two- and three hourly intervals for the second and third days respectively, when the treatment is stopped. The guiding idea is that if the specific bacilli can be hindered from rapidly multiplying at an early stage necrosis of the mucous membrane will not occur to any great extent, and time will be given for the production of natural protective substances, the treatment is stopped at the end of three days to counteract the evolution of a cresol and acid fast organism in the bacilli which may survive the early intensive treatment. Relapses can then be dealt with more successfully by the original method. In initially milder cases less frequent doses are indicated. If vomiting or retching is constant tr opii or tr chloroformi et morphinae co may be given, and opium is sometimes useful in the restlessness of late cases, but this should be used only in very special cases and if it is evident that the bowel has been completely emptied. Since marked thirst is present in the early stages, plenty of tepid water should be given between the medical doses. Care must be taken to raise the patient's head slightly, since a fatal issue may result from fluid entering the lung. In dry cholera cases with rapid collapse an injection of pituitrin may be given, if this does not produce prompt evacuation it may be followed by euterin or calomel. If stimulation is necessary adrenaline and camphor may be administered, but not more than three doses of either stimulant should be given. Palmer has also used this treatment, slightly modified, with beneficial results in bacillary dysentery, diarrhoea, and sprue.

80 Ether Inhalation in Tuberculous Peritonitis.

W E SAVAGE (*Anaesthesia and Analgesia*, May-June, 1928, p 137) observes that the cures obtained in tuberculous peritonitis by surgical intervention are out of all proportion to the work done, and enumerates the various theories advanced to account for this. A case which occurred some six years previously is cited, in which a patient with undoubted general tuberculous peritonitis showed immediate improvement with a rapid and uninterrupted convalescence and complete recovery after operation. This simple procedure would not of itself produce such a result, and the usual theories did not seem to apply in this case, hence, the only curative factor seemed to be the anaesthetic. As the result of this experience Savage has treated seven cases of this disease by ether anaesthesia, with six recoveries and one death. In three of these cases convalescence was apparently arrested, but after a second administration of the anaesthetic recovery was rapid. Savage suggests that one depends on the vascularity of the tubercle, and defines three stages in peritoneal tuberculous infection: a primary one of passive congestion, a secondary, in which the tubercles are small, isolated, and glistening, and a tertiary, or the stage of the large grey tubercle which tends to caseate and coalesce. The primary and secondary stages are vascular, and are apparently relieved by anaesthesia. In the case of recovery reported above the tubercles were found to be in the second stage, and in the fatal case in the tertiary. The author believes that chloroform will act equally as well as ether, and the other anaesthetic gases to a less extent, and that localized tuberculous peritonitis will also benefit by this treatment. He maintains that the cause of the relief or cure in these conditions is the anaesthetic and not the surgery, that if anaesthesia does not afford relief none need be expected, that it is of great prognostic value, and that the earlier in the disease it is employed the better.

81 Treatment of Mumps with Salvarsan

B DI LEONARDO (*Il Policlinico*, Sez. Prat., June 4th, 1928, p 1048) states that Kermorgant in 1925 isolated spirochaetes from the saliva of patients with mumps and found that injection of them into animals produced characteristic parotitis with localization in the testes in the course of forty eight to ninety six hours. Subsequently Pedro Ferreras obtained very good results in the treatment of mumps by the use of arsenobenzol and stovarsol in doses of 10 to 45 cg. Di Leonardo now records two personal cases, in a boy aged 13 and a girl now records two personal cases, in a boy aged 13 and a girl aged 16, in which the intravenous injection of 30 cg of neo-salvarsan in the former and 15 cg of "919" in the latter was followed by a rapid disappearance of the parotid swelling and other symptoms of mumps.

82. Influence of Synthalin on Glycaemia.

E TORRES (*La med Ibera*, June 9th, 1928, p 646), who records five illustrative cases, states that synthalin is a drug which produces hypoglycaemia, the degree of which is more marked in patients with large quantities of glucose in their blood than in those with mild diabetes and in normal individuals. Synthalin may be of special value in helping

patients to take a diet which would otherwise produce glycosuria, since its action on glycosuria is similar to that on glycaemia. Its therapeutic action may be summed up by saying that it produces all those effects which can be expected from its hypoglycaemic action, with the advantage over insulin that its action is slower and more persistent, and in therapeutic doses never produces hypoglycaemic coma. Moreover, the fact that it can be given by the mouth is considerably in its favour. Its influence, however, as an anti-diabetic is very doubtful, and its action on acidosis *in* *synthallu*, therefore, is chiefly indicated in mild forms of diabetes, in which the urine can be kept almost free from glucose and the patient allowed a fairly generous diet. In severe diabetes, however, *synthallu* cannot be entirely substituted for insulin because the doses required to remove the sugar from the urine would exceed the therapeutic dose. Torres concludes that the use of *synthallu* is restricted by its toxic action.

83 The Use of Convalescent Measles Serum

C. WESSELHOFF and F. J. GORDON (*New England Journ. of Med.*, May 24th, 1928, p. 752) proved by the following experiments that single doses of 5.0 cm of convalescent measles serum were efficacious in reducing the severity of a measles epidemic in scarlet fever and diphtheria wards. Among 76 patients exposed 25 controls were given no serum and all developed measles, 16 having severe attacks. Of 51 exposed with no history of measles who were given convalescent serum 14 (27.4 per cent) contracted measles, but only one of those had a severe rash. Broncho-pneumonia occurred twice in the control group and once in the group treated by serum. Intubation for measles laryngitis was necessary once in each group. Of these two patients the one in the control group died of broncho-pneumonia, and the serum-treated patient recovered without broncho-pneumonia.

Anaesthetics.

84 Mortality in Nitrous Oxide Oxygen Anaesthesia.

G. A. HAVEMAN (*Journ. Amer. Med. Assoc.*, May 26th, 1928, p. 1692) discusses the factors reducing mortality in nitrous oxide-oxygen anaesthesia, the condition of the patient, the measures taken to prevent shock and post-operative complications, and the effect of the anaesthetic being among the most important. From an experience based upon 3,057 thyroidectomies and 326 ligations the value of pre-operative treatment is emphasized, so that measures which are usually adopted after operation—such as transfusion, saline infusions, and the prevention of acidosis—should often be employed beforehand. Suggestions for the elimination of psychic shock whereby fear of the anaesthetic may be avoided are outlined. Nitrous oxide oxygen, where an inhalation anaesthetic is given, should be the choice, as being free from danger if the patient's colour is kept healthy and the heart is watched especially during induction, since there may be a tendency then to dilatation. The surgeon can give warning directly he notices the slightest change in the colour of the blood from bright scarlet, the anaesthetist can at once remedy the condition by giving more oxygen. The average time of the operation for thyroidectomy was thirty-seven minutes, and Haveman considers that the short time the patients were on the table had much to do with the low mortality rate of 27 deaths (0.88 per cent) of the 3,057 thyroidectomies. In the series of 326 ligations there were 4 deaths (1.22 per cent) all due to thyrotoxicosis, in none of the fatalities was the method of anaesthesia contributory, the 27 following thyroidectomy being mainly due to such conditions as acute thyrotoxicosis, haemorrhage, and malignancy.

85 Choice of Anaesthetics

L. MAIDITSCH (*Deut. Zeit. f. Chir.*, June, 1928, p. 287) states that during the last three years 11,400 operations have been performed at von Haberer's surgical clinic at Graz with ethyl chloride, ether, lumbar anaesthesia, local anaesthesia, and conduction anaesthesia, as well as combined local and splanchnic anaesthesia. His conclusions as to the value of these various methods are as follows. Ethyl chloride is excellent for short operations on septic cases but the anaesthesia should not be continued for long. Ether only was used for general anaesthesia, preceded by the open gas method, its dangers are generally exaggerated. In a large number of operations and individual cases it cannot be replaced by any method of equal value. Lumbar anaesthesia proved unreliable, and should, in Maiditsch's opinion, be used only in cases of emergency. Local and regional anaesthesia with cocaine avoided the drawbacks of general anaesthesia in a large number of cases. This particularly applied to operations on the upper part of the abdomen, which could be

performed under local anaesthesia of the abdominal wall combined with splanchnic anaesthesia according to Brann's method, with almost complete avoidance of any pain. As regards the incidence and mortality of pulmonary complications following operations on the upper part of the abdomen, combined local and splanchnic anaesthesia were found to offer no advantages over general anaesthesia. In most operations, Maiditsch adds, the choice of the anaesthetic should be determined by the special circumstances of the case in preference to a rigid schematization of anaesthetics for the various kinds of operations.

86

Spinal Anaesthesia

B. RAPPOPORT (*New England Journ. Med.*, April 19th, 1928, p. 447) records his observations on spinal anaesthesia, with a report of 500 cases. Slight failure is due to some error in technique, only experienced anaesthetists should practise spinal anaesthesia. Its use is contraindicated in children, young adults, the nervous, and patients suffering from shock, old people respond well, and a low blood pressure is not necessarily a contraindication. After a preliminary hypodermic injection of morphine, with the patient in a sitting posture and the head bent forward, the third and fourth interspaces are selected, and the needle is inserted into the fourth interspace for operation on the lower extremities, perineum, and rectum, into the third for bladder operations, into the second for abdominal operations below the umbilicus, and into the first for all upper abdominal operations. After allowing 5.0 cm of spinal fluid to escape the anaesthetic solution is injected slowly, and after withdrawal of the needle the patient is put on his back in a slightly Trendelenburg position. Analgesia should appear in from two to fifteen minutes, but should it fail to be present in twenty minutes the process may be repeated with the same dose in the next interspace. The author finds that a dose of 0.075 gram novocaine generally suffices, dissolved in 5.0 cm saline solution. Serious complications rarely arise, and there is usually no headache or unpleasant after-effects. Rappoport considers that when employed by a competent anaesthetist thoroughly conversant with the technique spinal analgesia is ideal for many patients with heart, kidney, or lung trouble, for those suffering from diabetes or sepsis, and for the aged.

Obstetrics and Gynaecology.

87

Diabetes of Ovarian Origin

CARNOT, TERRIS, and CAROLI (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, May 17th, 1928, p. 738) describe the case of a married woman, aged 36, in whom diabetes had not been relieved by anti-diabetic diet. The glycosuria amounted to approximately 100 grams daily, acetone and diacetic acid were sometimes present. The blood sugar was never more than 2 grams. The patient lost more than 22 lb in weight in two months and became much weaker. Two preparations of insulin were administered without result, except that diacetic acid disappeared from the urine. Prior to the first symptoms of diabetes menstruation was delayed, scanty, and finally absent, but before it ceased altogether it was noticed that the glycosuria increased a few days before the period. Apparently the ovarian endocrine action reduced the quantity of blood sugar. An ovarian extract was injected in doses of 1.0 cm every second day. After the second injection a rapid fall in the glycosuria occurred, and the patient's ovarian pain disappeared. The general health improved rapidly, and the patient gained 11 lb in ten days, menstruation reappeared normally after an absence of three months. The patient lost the saccharine taste in her mouth and her excessive hunger. Some days after the last injection of ovarian extract glycosuria increased, but it was reduced by a further series of hypodermic injections. The authors conclude that there is a close relationship between ovarian disturbances and diabetes, and that ovarian extract may reduce glycosuria and hyperglycaemia when insulin has failed.

88

F. RATHERY and M. RUDOLF (*ibid.*, p. 741) state that insulin seems to play an important part in ovarian function. Recent researches have indicated that a close connexion exists between the internal secretions of the pancreas and of the ovary. The authors confirm the observation that insulin relieves menorrhagia and emaciation when accompanied by amenorrhoea, it also relieves the intractable vomiting of pregnancy. They have conducted a number of animal experiments and also made clinical observations. They conclude that during the menstrual cycle in diabetic patients there appears to be a period when patients are especially sensitive to insulin, that period is the premenstruum and the first days of menstruation, when folliculine is very abundant in

the blood. Combined insulin folliculin medication has produced in two patients a reduction in glycosuria and a distinct diminution in the excretion of acetone and ketone bodies, in one case the blood sugar was also reduced. When both patients received large doses of folliculin the contrary effect was produced. In a third patient, a child who had never menstruated, the treatment had no effect on the glycosuria, and but little on the acetone. The blood sugar increased definitely. The authors agree with Carnot, Terris, and Catell that in diabetic women folliculin influences carbohydrate metabolism.

89 Latent Sepsis in Pregnancy Toxaemia.

FRANCES IVENS (*Journ. Obstet. and Gynaecol. Brit. Emp.*, Summer No. 1, 1923, p. 307) regards the toxæmias of pregnancy—namely, oedema, albuminuria, hyperemesis, accidental haemorrhage, jaundice, and eclampsia—from the standpoint of general pathology as probably bacterial in origin, and records the results of bacteriological examination of the urine in such cases. Coliform organisms, usually associated with pus and sometimes with blood, were present in thirteen cases with albuminuria and oedema, in two with pernicious vomiting, and in two with jaundice and hyperemesis. In two cases of accidental haemorrhage coliform organisms and streptococci were found, and staphylococci and streptococci in two others, while in a fifth, in which there was suppression of urine, coliform organisms and streptococci were recovered from the placental tissue. The author considers that the part played by autogenous infection, especially when associated with the trauma of delivery or with a lowered resisting power during pregnancy and the puerperium, is important, since the richly vascular retro-placental areas constitute a favourable site for the rapid multiplication of organisms should a latent infection become active. It is suggested that the jaundice of pregnancy, and even of acute yellow atrophy, may be due to the spreading of *B. coli* to the bile ducts, and that it may also be responsible for the haemorrhagic vomit of the terminal stages of pernicious vomiting, which resembles that seen in *B. coli* septicaemia.

90. Utero-salpingography

J. JARCHO (*Surg., Gynecol. and Obstet.*, June, 1923, p. 752) reports further studies on the action of the "tubal sphincter", he also describes a syringe for transuterine injection, and discusses the therapeutic use of iodized oils within the uterus and Fallopian tubes. It has been shown by Henser that the uterine cavity possesses a salpingo-uterine sphincter, and that the muscular contraction of the tube extends to the uterine cavity, thus causing iodized oil in the peritoneal cavity, after absorption by the tube through capillary attraction, to be expelled into the uterine cavity. This sphincter remains open when there are remnants of placenta, thus accounting for ascending infection. In order that the danger of forcing septic material through the ambricated extremity may be avoided, Jarcho adds that the oil should be injected slowly and carefully under fluoroscopy, using a syringe specially adapted for the transuterine injection of iodized oil, and having a manometer attachment. A pressure of 30 to 40 mm. of mercury is sufficient, and the amount required to fill the uterus and tubes averages 4 to 5 c.c. The procedure is said to be safe and harmless, it supplements, and frequently supplants, the insufflation of gases in gynaecological diagnosis, in some cases affording exact information as to the condition of the genital tract which cannot be obtained by any other means. Diagnosing occlusion of the tubes with localization of the site being the most valuable use of utero-salpingography, Jarcho considers that the transuterine injection of iodized oil has also a definite therapeutic value in subacute and chronic conditions of the tubes, he describes a case in which utero-salpingography showed dilatation and occlusion of both tubes, though ten months later the picture was normal, a result which he attributes to the therapeutic effect of the slow liberation of iodine within the tubes.

Pathology.

91 Lymphadenoid Goitre.

REFERRING to a previous paper in which an experimentally produced goitre, unrelated in its origin to iodine deficiency, is described, R. MCCARRISON (*Indian Journ. of Med. Research*, April, 1923, p. 909) discusses a further series of experiments which were undertaken, partly to confirm his previous observations, and partly to ascertain whether deficiency of manganese plays any part in the production of this type of goitre. In 1925 Williamson and Pearce described a like condition in man, and defined lymphadenoid goitre as the hypertrophic reaction of a physiologically insufficient organ with which there occurs a preponderance of lymphocytosis

aggregates, fibrosis, and a peculiar atrophy of the parenchyma. The condition can be focal and non-follicular, and, in contrast with the toxic symptoms of Graves's disease, is associated with symptoms of myxoedema. In the present experiments rats were employed, these were fed on three different diets, all of which were deficient in both manganese and vitamins. Lymphadenoid goitre, similar to that described by Williamson and Pearce, was produced in these animals, and McCarrison believes that this disease is not due to deficiency of iodine in the food, but to an insufficiency of vitamins of the A, B, C, and D classes associated with a deficiency of certain inorganic elements, of which manganese appears to be one. In man it may be expected to occur in young and growing persons who subsist on diets composed largely of white flour poor in manganese and vitamins or other vitamin poor carbohydrates, protein, and fats, with a paucity in, or absence from, the diet of fresh fruits and green leafy vegetables. Such diets, judging from their effects on rats, induce in the thyroid gland a state of physiological subnormality which is the basis of lymphadenoid goitre.

92. Tuberculin Sensitivity and Immunity to Reinfection.

M. NASTA (*C. R. Soc. de Biologie*, May 21st, 1923, p. 1462) infected a number of guinea pigs with 0.001 mg. of bovine tubercle bacilli, the inoculations were made subcutaneously in front of the shoulder. At intervals afterwards ranging from six to forty days the intradermal tuberculin test was performed on the skin of the abdomen, and 0.01 mg. of the same strain of tubercle bacillus was injected into the skin of the thigh. One set of guinea pigs was exposed to ultra violet rays from the date of the first infection up to the time of reinfection. In the non-irradiated animals the tuberculin test became positive after about seventeen days, when a positive reaction was obtained with a dilution of 1 in 50, the sensitivity increased, till after forty days the injection of only a 1 in 500 dilution resulted in actual necrosis. The reaction to reinfection, marked chiefly by abscess formation, ulceration, and tendency to spontaneous cure, was strongest during the second, third, and fourth weeks, subsequently it diminished in severity till after forty days only a small non-ulcerating nodule followed the reinfection, though a larger dose of tubercle bacilli, 0.1 mg., resulted in a typical Koch's phenomenon. At the same time as the severity of the reaction diminished, the time at which the reaction appeared decreased from nine to two days. Nasta concludes that the maximum reactivity to reinfection occurs earlier than the maximum hypersensitivity to tuberculin, and therefore believes that the tuberculin test is no index of immunity. The animals exposed to ultra violet radiation developed a much lower degree of sensitivity to tuberculin, and on the whole reacted less to reinfection.

93 The Mechanism of Infection in Anthrax.

G. ROYDA and E. SCHWARZ (*Lo Sperimentale*, June 16th, 1923, p. 173) discuss the question whether it is possible for infection in anthrax to occur by the intestinal tract. They recall the views of different workers. Pasteur held the view that the spores gained access to the body through minute lesions in the buccal and pharyngeal mucosa, Koch believed that the spores passed through the stomach, developed into vegetative bacteria in the intestine, and then passed through the intestinal mucosa into the blood, Besredka teaches that anthrax spores or bacilli are harmless unless they come into contact with lesions of the skin, and Sanarelli denies that the spores are able to germinate in the intestine or to pass through the intestinal mucosa. The present authors have performed a number of experiments to ascertain which of these views is correct. Forty guinea pigs were infected by the direct injection into the oesophagus of a suspension of anthrax bacilli, the injection was made by a semi-rigid catheter, care being taken not to harm the mucosa. The suspension of anthrax consisted of a third of a twenty-four hour agar culture in 5 c.c. of saline. The guinea pigs were infected in the fasting condition, but directly afterwards were put on to a normal diet. At times varying from two to seventy-two hours after infection cardiopuncture was performed on each animal, and cultures made from the blood. Of the 40 animals 25 survived, 3 died from cardiopuncture, 4 died without anthrax bacilli being found in the blood at the necropsy, and 8 died with bacilli in the blood post mortem. Only one animal gave a positive blood culture during life. In another series of twenty guinea pigs the animals were given one or two preliminary doses of ox bile; in this series only two animals died in which bacilli were found in the blood post mortem. The authors conclude from these experiments that anthrax bacilli are unable to traverse the intestinal mucosa, and that primary intestinal anthrax does not occur. They think that the deaths from anthrax septicaemia following the introduction of the bacilli into the oesophagus are probably due to the entrance of bacilli into the respiratory tract and their subsequent invasion of the blood.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

97 Variations of the Blood Pressure in Tabes Dorsalis

A DUMAS, R TROUVET, and Milo MERCIER (*Journal Méd de Lyon*, June 5th, 1928, p 303) remark that in tabes dorsalis frequent variations in blood pressure occur, apart from gastric or other crises. A considerable instability of blood pressure is also found during examination: this appears to be due to sympathetic disturbance. It is assumed that this abnormal fluctuation of arterial tension in tabetic patients is connected with the abolition of reflexes which normally permit the heart to adjust itself to the varying conditions of the peripheral circulation. This is supported by the fact that the hypodermic injection of adrenalin produces in tabetic patients an abnormal fall of blood pressure, in three of the authors' cases this fall amounted to 70 mm of mercury. In other diseases of the central nervous system involving the sympathetic centres in the medulla, such as syringomyelia, a similar instability of blood pressure is observed occasionally, resembling that found in tabes dorsalis. The authors have fifteen tabetic patients under observation. They find that these frequent variations are not connected with the occurrence of painful crises, and that they are present in many patients who do not suffer from such crises. They conclude that among the usual cardio-vascular symptoms of tabes must be included the abolition of the oculo-cardiac reflex: this is particularly striking in patients who have frequent attacks of tachycardia. They observe that it would appear that the cardio-vascular system fails to act in such cases in accordance with the laws of Marcy.

98 The Spleen in Alcoholic Cirrhosis.

H DUFOUR and BOURGEOIS (*Rev Méd Franç*, June, 1928, p 455) review the literature and record observations on forty-five cases of cirrhosis of the liver, with special reference to the question of enlargement of the spleen in alcoholic cirrhosis. Their conclusions are as follows: In alcoholic cirrhosis the spleen is not increased in size in at least one-third of the cases, the part played by obstruction to the circulation is very slight and cannot by itself explain the splenomegaly. The splenic enlargement is the result of an acute or chronic toxic infection, which may be specific (malaria, tuberculosis, or syphilis). In alcoholic cirrhosis, if there is not an obvious coexistent infectious disease, the presence of a large spleen is in favour of coexistent syphilis.

99 Pleurisy as a Complication of Pulmonary Tuberculosis

J F BRATT (*Tidsskr f d Norske Lægefor*, May 1st, 1928, p 408) has analysed the 3,380 cases of pulmonary tuberculosis treated at the Vossnes Sanatorium in Norway during the past ten years with reference to the frequency with which this disease was complicated by pleurisy before and during residence in the sanatorium. In 1,031 cases, or 30.5 per cent, there was a history of pleurisy; the incidence of which on the two sides was approximately equal. As a rule the pleurisy occurred on the side most affected. In 3.01 per cent the pleurisy was bilateral, and in 1.6 per cent there was more than one attack of pleurisy. It was serous in the overwhelming majority of cases, and it was dry in only about 20 per cent. It was more frequent in men than in women, 34 per cent of the men and 26 per cent of the women suffering from this complication. In a chart showing the relation of the outbreak of an attack of pleurisy to the first clinical appearance of pulmonary tuberculosis the author indicates how the frequency of these attacks increased with the approach of the clinical manifestation of pulmonary tuberculosis. In many cases the outbreak of the pleurisy and the diagnosis of pulmonary tuberculosis were synchronous. The months in which attacks of pleurisy were most frequent were December and April and the periods during which the average gain in weight of all the patients was least were those in which the attacks of pleurisy were most frequent. Most of the patients were between the ages of 15 and 25. With regard to the prognosis, the cases of pleurisy were classified according as the patients were sputum positive or sputum negative, and their subsequent fates were compared with those of the patients without pleurisy in the same two classes. The mortality and fitness for work from one to ten years after discharge were practically the same for the sputum positive patients, whether they had suffered from pleurisy or not. But the sputum negative patients without a history of pleurisy fared considerably better than the sputum negative patients with such a history.

57 Physical Signs in Bundle branch Block.

T T KING (*Amer Heart Journ*, June, 1928, p 505) has investigated the possibility of diagnosing bundle branch lesions without the aid of electro-cardiography. From a review of the literature on experimental heart block in dogs, and as a result of critical analysis of the clinical findings reported by various observers in established cases of bundle branch block, the following hypothetical clinical picture was constructed: visible and palpable reduplication of the apical systolic thrust, muffling of systolic sounds at the apex and reduplication of the first sound at the apex, or a single first sound with an asynchronous systolic murmur, or, sometimes, asynchronous apical systolic murmurs. These signs are of greater significance if the blood pressure is normal. One hundred unselected cardiac cases were examined for bundle-branch lesions on the basis of the signs described. Such lesions were subsequently shown by the electro-cardiogram to be present in nine patients, and of these six had been recognized at the bedside, while two of the remaining cases were diagnosed correctly by a majority of observers. In only four of the aforesaid cases proved not to have bundle lesions were the typical signs found, and two of these with marked hypertension were considered to have presystolic gallop rhythm. The authors find that in doubtful cases reduplication of the systolic apical thrust may be rendered visible through the medium of a cloth laid over the chest. Factors in the differential diagnosis from hypertension with presystolic gallop rhythm are elevation of blood pressure and loud heart sounds which occur in the latter condition while soft, almost inaudible, apical systolic sounds, with sometimes reduplication of the second sound, are characteristic of bundle-branch lesions.

99. Diphtheria of the Penis.

J F PRINZING (*Journ. Amer Med Assoc*, May 19th, 1928, p 1620), who records a personal case, illustrates the rarity of the condition by his having found only two previous cases on record—reported by Cochrane in 1920 and Bode in 1921 respectively. Prinzling's patient was a man, aged 28, who developed considerable swelling of the penis and a tight phimosis on retraction of the prepuce severe balanoposthitis was found. Cultures for diphtheria bacilli were positive for the penis, but negative for the throat. Antitoxin treatment was given, 20,000 units being injected intramuscularly and 10,000 locally. Immediate improvement followed, and although secondary infection of the penis occurred six weeks after admission, recovery resulted. Cultures from the vagina and throat of his wife were positive, she was given 10,000 units of antitoxin. No sequelae are reported.

Surgery.

99 Complete Excision of the Right Cerebral Hemisphere.

OWING to the impossibility of diagnosing the exact limits of a malignant cerebral tumour, J LHERMITE (*L'Encephale*, April, 1928, p 314) believes that the logical surgical treatment of these growths is complete excision of the hemisphere, and not merely a localized exceresis. Dandy of Baltimore, who first attempted this radical measure, has shown that many patients with neoplasms of the right hemisphere can undergo considerable resections of the temporal or occipital lobes without any pronounced lessening of the mental functions, and that, since these patients usually suffer from left hemiplegia, complete excision of the hemisphere should cause no greater disorders than if the tumour were left to evolve untreated, or attempts at incomplete removal or radiotherapy were made. Removal of the right hemisphere is alone possible, the left being the seat of the intellectual powers. The great danger of the operation is said to lie in haemorrhage from the cerebral arteries and sinus venosus, the possible subsequent complications of secondary haemorrhage and infection can be avoided by a perfected technique. Dandy's method is described, and five of his cases are reviewed. One patient died three months after operation from a recurrence of the growth. One in forty-eight hours from haemorrhage, due to the suture on the middle cerebral artery becoming loose, and one in two weeks from pneumonia. Another patient survived for three and a half years, and then succumbed to a recurrence due to the leaving of a fragment of the tumour at the base of the brain. In none of these

cases was there any mental disturbance. In the remaining case the tumour lying deeply in the hemisphere and entirely surrounded by normal tissue, was removed *in toto* at the operation. This patient is still living, and may be regarded as cured. The following facts have been noted following the operation. The homiplegia of the left side of the face is only relative and the force of the masticators is unaffected, that of the limbs remains flaccid or is very slightly spasmodic. Differential sensibility is abolished on the trunk and all the extremities, the patient correctly perceiving only profound and intense stimuli. Sensation is much better preserved in the face, and it would appear that the atbrokinetic sensibility is much less affected than other kinds. Gustatory sensations are present on the anterior two thirds of the tongue, and addition remains unimpaired but left hemianopsia is absolute. This relative or perfect conservation of certain perceptions can be explained by two hypotheses: either sensation and perception is effected by the left hemisphere or the optic thalamus possesses a function of elementary conscious sensibility. The author believes that both these factors come into play. The patient shows no disorders of the mental or vegetative functions, and no muscular atrophy, arthropathy, or scarring. This case is held to prove that the seat of all conscious activity does not lie solely in the cortex, but is concerned to an equal extent with the subcortical centres, and that the higher faculties are associated, not with any particular centre, but in the entire brain.

100 Perforation in Carcinoma of the Stomach

J CHAVANNAZ and S RADOVITCH (*Rev de Chir*, No 2, 1928, p 111) remark that perforation of a gastric ulcer is frequently seen, but that perforation of a carcinomatous growth of the stomach into the peritoneal cavity seems to be but seldom recognized. He records 47 cases of perforation of malignant growths of the stomach, and the following conclusions are drawn. This rare complication usually occurs in elderly patients and in males, who appear to be more commonly affected with cancer of the stomach. The perforation is always found in the anterior aspect of the stomach and near the pylorus. The symptoms in many cases are similar to those of perforation of a simple ulcer. On the other hand, the signs may be much less marked, the condition may be entirely unrecognized, and the fact of perforation be only discovered after death. When the condition is detected early the ideal treatment is gastro-pylorectomy. The mortality in cases of perforation is about 50 per cent.

101 Prognosis in Cancer of the Breast

R LEROUX and M PERROT (*Bull de l'Assoc Franç pour l'Etude du Cancer*, April, 1928, p 180) publish records of twenty-seven cases of cancer of the breast, with special reference to the reaction of the tissues to methyl carmalum stain and the histological appearances of the connective tissue stroma. They believe that cases in which the tissues stain well with carmalum have a better prognosis than those which do not take up the dye. In favourable cases the stroma shows abundant lymphoid infiltration, good staining of the intercellular substance, and fibroplastic metaplasia of the fat, while the reverse of this is to be seen in unfavourable cases. Illustrations are given of the histological appearances in the two types of case.

102 Hydatid Cysts of the Lungs

H GABRIELLE and PAITRE (*Lyon Chir*, March-April, 1928, p 176) report a case of two hydatid cysts of both lungs. The patient was an Algerian soldier, who was admitted to hospital suffering from coughing attacks, loss of weight, and respiratory difficulties which led to a diagnosis of tuberculosis. Further examination showed signs of pleurisy at the base of the right lung and diffuse congestion of both lungs. As the result of tapping and examination of the fluid drawn off, which showed no trace of tubercle bacilli, the diagnosis was in doubt. The cough grew less, the temperature fell, and the expectorations were less evident, though the difficulty with breathing remained. New symptoms then appeared—namely swelling of the face, dilatation of the jugular veins, and enlargement of the thorax, which on the right side showed a definite bulging at the base. Further examination revealed signs of pulmonary consolidation, which, with other symptoms, indicated the possibility of hydatid cysts one in the lower lobe of the right lung and the other in the upper lobe of the left lung, which was confirmed by the removal of typical hydatid fluid. Surgical intervention on two separate occasions revealed two large cysts, which were both evacuated. Drainage was employed and the patient made a satisfactory recovery. It is concluded that hydatid cysts are more common among soldiers than among the civil population, that they can remain dormant for some time and that they may cause compression of the lung and the superior

vena cava, with slight swelling of the face and dilatation of the veins of the neck. Diagnosis from tuberculosis is difficult, radiographic examination being the most reliable test, in conjunction with an exploratory tapping, though the latter aggravates the symptoms considerably. As regards the operation a local anaesthetic is sufficient, and the approach should be made through an intercostal space after the removal of a rib. A drain should be left for a few days, particularly in the case of suppurating cysts.

Therapeutics.

103 Injection Treatment of Varicose Veins

S WIDERÖE (*Tidsskr f d Norske Lægefor*, April 15th, 1928, p 360) has treated 140 patients suffering from varicose veins, giving them intravenous injections of a 25 or 30 per cent solution of sodium salicylate, or one of the preparations in common use for this purpose, such as quinine with urethane. The injections were given under ambulatory conditions, and their total number was 295. Several patients received only one injection, and the greatest number of injections given to the same patient was eleven. This patient was an unmarried woman, aged 40, whose bilateral varicose veins had existed since she was 18. Some of them were as thick as a finger. The results were excellent, and she was able to remain at work throughout the treatment. In every case the injections provoked complete or partial obliteration of the veins, and the smaller veins often became obliterated without thrombosis. An ascending phlebitis of the thigh occurred in several cases, and in 2 it was so painful that the patients experienced some difficulty in walking, one of them had to remain in bed on this account. Necrosis at the site of injection was a sequel in 6 cases, in 5 of which the injected substance was sodium salicylate. In 4 cases the necrosis was quite slight, and the patients were able to attend to their work, they felt no discomfort, neither the necrosis itself nor the subsequent repair of tissues being painful, but in 2 cases the necrosis was severe enough to entail the patients' admission to hospital, recovery requiring three weeks in one case, and four in the other. In no case was the necrosis complicated by phlegmon or fever, and pulmonary embolism was never observed. In 5 cases the patients suffered from varicose ulcers, which were comparatively small, and which healed during or after the treatment. In 2 out of 3 cases of eczema this condition cleared up completely. Five of the 140 patients had previously been operated on, the cure effected by the injections in these relapsing cases was complete. None of the patients re-examined since the author began this treatment in January, 1926, showed any sign of relapse. The youngest patient was 21, the oldest 68. In several cases the treatment was undertaken for cosmetic reasons, the present fashions of mixed bathing and short skirts with silk stockings having rendered the possession of varicose veins more distressing than heretofore.

104 Antipneumococcal Serum in Lobar Pneumonia

W H PARK and GEORGIA COOPER (*Journ Amer Med Assoc*, April 28th, 1928, p 1349) discuss the method of administration and dosage of antipneumococcal serum in lobar pneumonia. They consider that the best route for administration is undoubtedly the intravenous, because the whole amount of antibody injected becomes immediately available, whereas if given intramuscularly a period of one or two days is required for its gradual absorption. The latter method is only useful when for any reason there is danger in giving the refined or unrefined serum intravenously. The authors advise that each patient on admission should receive 10,000 units of Type I and of Type II antibody, these doses should be repeated every eight to twelve hours so long as the temperature remains high or if septicaemia is present. When the type of the pneumococcal infection has been determined a monovalent serum may be substituted for the polyvalent one, and if the pneumonia is due to a Type IV pneumococcus treatment should stop with the third injection. Should the temperature after falling rise again to 102° F the injections should be repeated unless abundant antibodies are shown to be present or the rise is obviously due to complications such as serum sickness, streptococcal abscess, or other conditions not likely to respond to antibody injections. J G M BULLOWA (*ibid*, p 1354), in a consideration of the use of antipneumococcal refined serum in lobar pneumonia, outlines the data necessary for a comparison between cases treated with serum and those not so treated, and insists on the importance of having a good control series. Such an adequate and comparable series can be obtained by alternating patients and rating their severity on admission, the size of the series requisite for correct conclusions to be drawn is determined by a consideration of the standard error. In alternating patients the order of arrival in the ward alone determined

whether serum was to be given or not. It was found in such a controlled investigation that not only did serum treatment reduce the mortality but it shortened the illness of those who recovered, the advisability of administering polyvalent serum as early as possible without awaiting the result of typing was clearly shown.

Radiology.

105 Treatment of Angina Pectoris by Deep X Rays

F C ARRILLAGA (*Bull et Mém Soc Méd des Hop de Paris*, Jan 7th, 1928, p 949) has treated eight patients suffering from angina pectoris with deep x rays, and reports good results from the method. The cases selected for treatment were all of severe grade and had previously resisted the usual therapeutic measures. The first patient, whose blood pressure and valves were normal, was given five precordial applications over a period of six weeks. In the eighteen months following this treatment there was no recurrence of attacks. Another patient was relieved of attacks which previously followed even slight exertion. Radiation was applied in each case from the front and back over an area corresponding to the heart and aorta. The first series of radiations was followed, thirty or forty days later, by a second, generally, at the time of the latter, no further attacks were occurring. The author believes that these results are due to diminution of excitability or physiological action of the third cervical and the stellate ganglia and their ramal communications. Although the usual sequelae, such as headache, nausea, and prostration, are not uncommon, electrocardiography has revealed no myocardial changes in those subjected to deep x rays, nor have microscopic abnormalities been observed in experiments upon animals. Clinical and experimental evidence also goes to show that deep x rays in the doses used on these patients cause no notable effect upon the blood. General therapeutic measures, including anti-spasmodic drugs and dieting, should be continued during treatment, as also should the specific treatment of syphilis if this disease is present.

106 Radiological Diagnosis of Pelvic Disease.

F L STONE (*Amer Journ Obstet and Gynecol*, May, 1928, p 662) advocates the use of lipiodol with x rays as a diagnostic aid in gynecology. He gives the warning, however, that lipiodol injection into the uterus and tubes necessitates rigid asepsis, while the possibility of forcing material into the pelvic cavity must be borne in mind, though this danger is not so great as might be thought. Acute conditions of the cervix must be first treated, and bleeding patients, if injected at all, require cautious handling. An inflammation may precede the injection, depending on the information desired. An all glass, or Record, 10 c cm syringe filled with lipiodol is attached to the cannula used for insufflation, and sufficient pressure is exerted against the cervix to prevent any back flow. When the uterus is freely movable it may be necessary to pull it down with a tenaculum against the rubber acorn in the cervix. Patency of the tubes can often be determined by the ease with which the oil passes in, but as the material fills the uterus, especially when there is occlusion, some pain may be felt, this passes off if the pressure of the injection is delayed for a short time, after which the procedure can be completed without discomfort. Two skiagraphs, one taken immediately after injection and the other soon after this and before removal of the cannula, will show the progress made in tubal filling, while a third, taken after removal of the instrument, demonstrates the rapidity with which the uterine cavity empties. Stone considers that the method has no equal as a means of determining tubal patency, he adds that it will aid in diagnosing functional conditions and in deciding when surgical relief is indicated in many cases of sterility.

107 Standards of Protection against X Rays.

A MUTCHELLER (*Radiology*, June, 1928, p 468) lays it down that the stray radiation dose to which the average radium or x ray worker can safely be exposed should not exceed one hundredth of an erythema dose. A dental film wrapped in black paper and carried by the operator under his clothes on the front part of his chest for about one week is then developed and compared with a control film, this procedure provides the operator with a simple method of testing the erythemic dosage to which he is exposed in his work. The total thickness of lead recommended for adequate shielding of the tube is as follows, (1) For radiography, not less than 2 mm. (2) For fluoroscopy, not less than 2 mm. (3) For superficial therapy, not less than 3.25 mm. (4) For deep therapy, not less than 5.6 mm. When the x ray tube is only partly enclosed stray radiation intensity is so great that only one tenth of the amount of work possible with a completely enclosed equipment can be attempted.

Obstetrics and Gynaecology.

108 Scopalamine Anaesthesia in Obstetrics

DISCUSSING the disfavor into which narco anaesthesia produced by injections of scopalamine and morphine has now fallen, BERTHA VAN HOESSEN (*Anaesthetes and Analges*, May-June, 1928, p 151) states that the method is supposed to cause asphyxiation of the newborn, but in her view the morphine is entirely responsible for this. Formerly, narco anaesthesia was produced by injecting 1/4 grain of morphine with 1/150 grain or even less of scopalamine. The method now followed by the author is to give, as soon as labour starts, 1/100 grain of scopalamine alone, and to repeat this dose twice at intervals of half an hour. This dosage is said to be sufficient to produce anaesthesia with complete unconsciousness. If the anaesthesia is to be maintained for an indefinite period, these doses should be given at two-hourly intervals from the last of the three initial doses. In twenty six cases of narco-anaesthesia, eleven being primiparae and fifteen multiparae, all the babies were in excellent condition at birth with the exception of one—a breech case—which needed resuscitation. In the primiparae the average length of labour was seven and a half hours, and in the multiparae three and a half hours. The average loss of post-partum blood was 90 c cm. The advantages of this method are the shortening of labour and decrease in the loss of post-partum blood, the anaesthesia brings about perfect unconsciousness, stimulation of the uterine contractions, and relaxation of the sphincters, the administration of the anaesthetic does not require constant personal attention, and the patient awakens with a sense of well being and freedom from pain and fatigue. The risk of the patient, owing to her unconscious state, disturbing sterile wrappings at the time of delivery, is averted by suitably and comfortably securing her legs and arms, the objection that one half to three quarters of an hour are consumed in producing narco-anaesthesia can be satisfactorily met by giving nitrous oxide during the pains until the scopalamine has had time to take effect.

109 Inflammation of the Pouch of Douglas

J L HENROTAY (*Braz Méd*, June 3rd, 1928, p 1007) reports a case with the object of directing attention to the fact that inflammation of the pouch of Douglas is a definite entity which, according to him, was first studied by R Condomin and his school. The condition is characterized by a retraction of the utero-sacral ligaments and the ultimate disappearance of the posterior vaginal cul de sac, associated with definite genital pain. A predisposing factor in inflammation of the pouch is that it is the lowest part of the abdominal cavity, and that therefore all the exudative secretions of the abdominal organs gravitate there. The author admits that it is doubtful whether the inflammation of the subserous cellular tissue is due to a primary form of infection in the adjoining uterus or cervix, or to the absorption of infectious or irritant fluids which have accumulated in the serous sac above. Nevertheless a condition of progressive retraction of the cellular tissue and the utero-sacral ligaments is clinically demonstrable. It is always associated with much pain, which is the first complaint made by the patient. In Henrotay's case the patient complained of intolerable pain radiating towards the rectum and anus. Various medical treatments had been tried for three months without success. After examination an adenoma, beginning to involve the rectum was suspected, though nothing definite was detected. When the abdomen was opened the pouch of Douglas was found to contain a lemon coloured serous fluid. The peritoneum covering the rectum and posterior surface of the uterus was covered with tiny points of subserous effusions of blood. There was no growth, and the adnexa were normal. Total hysterectomy seemed to offer the only chance of cure, and was therefore performed. The patient left hospital at the end of fourteen days entirely relieved of her former pains. This was the procedure advised also by Condomin for cases unrelieved by medical means.

110 Sarcoma of the Uterus

R H MILLER and H ROGERS (*New Eng Journ Med*, June 21st, 1928 p 927) observe that most cases of uterine sarcoma are only discovered during or after an operation for fibroid tumours. They review the literature on the subject, and analyse 2 043 cases of fibroma occurring in the Massachusetts General Hospital during thirty years, of these, 25, or 1.2 per cent, proved to be sarcoma. The average age of the patients was 46, the oldest being 64 and the youngest 28. The spindle celled variety was present in almost half of the cases, other forms found being the myxosarcomatous, the round and spindle-celled, and the round celled, which is considered the most malignant. The usual site of sarcoma

is the fundus, only about 12 per cent being found in the cervix. Seven, or 28 per cent of the cases had local metastases, or extension of the growth, outside the uterus. The parametrial tissues, great omentum, and peritoneum of the small bowel were the structures involved, but no distant metastases were noted. Mitosis, according to Evans an indication of the malignancy of sarcoma, was present in only 4 cases. In 9 (36 per cent) there were concomitant fibroids, and it is assumed that sarcoma may, but not necessarily, originate in a pre-existing fibroma. Uterine sarcoma presents no pathognomonic symptoms and is usually mistaken for myoma. The authors advise that any rapidly growing fibroid should be suspected of being sarcomatous, every specimen should be carefully examined at the time of operation, and, if found sarcomatous, the operation should be very radical. The *post mortem* report in one case is given, and a striking and typical case of great malignancy is also reported.

111 Exploratory Puncture of the Vagina.

ACCORDING to F. MONTUORO (*Riv. d' Ostet. e Ginecol. Prat.*, April, 1928, p. 150) puncture of the vagina is an easy and safe manoeuvre in cases in which it is desired to ascertain the nature of an exudate in the pouch of Douglas or the parametrium, or of the contents of a tumour situated in either of these places. A 5 or 10 c. cm. syringe should be used having a wide needle at least 5 cm. long. The patient should lie on her back with widely abducted thighs, pressure on the hypogastrium by an assistant increases the visibility of the swelling and adds to the simplicity of the operation. If blood, serum, or blood stained serum is obtained the needle is withdrawn and a sterile tampon applied. If, on the contrary, pus is found the needle is left in position as a guide to the incision, which should be transverse, and be widened if necessary by means of a guarded bistoury. Puncture of the lateral fornices is indicated whenever suppurative exudate of a purulent parametritis or paracolpitis. In performing lateral colpotomy the ureter has sometimes been damaged, and it is important that the incision be transverse, not longitudinal. As examples respectively of the uses and limitations of exploratory vaginal puncture Montuoro describes the two following cases. A woman who had suffered from malaria, gonorrhoea, and adnexal inflammation had a swelling in the pouch of Douglas with signs of peritoneal irritation and acute anaemia. The recent history suggested a diagnosis of ectopic pregnancy, and the remote history one of gonococcal pelvic peritonitis. Exploratory puncture gave issue to sero-sanguineous liquid, and laparotomy confirmed the diagnosis of tubal pregnancy. In the second case the patient, whose menses had been retarded a few days, had pain in the lower abdomen, vomiting and fever, a tender swelling was palpable in the pouch of Douglas. Ruptured tubal pregnancy was suspected, but anaemia, vaginal bleeding, and expulsion of the decidua were absent. An exploratory vaginal puncture gave vent to blood stained serum, and an operation was performed for ectopic gestation. The opened abdomen, however, showed a multilocular ovarian cyst twisted on its pedicle, the needle had punctured one of several loculi which contained serous fluid into which blood had been effused.

Pathology.

112. Etiology of Yellow Fever

A. PETTIT and G. STEFANOPOULOU (*C. R. Soc. de Biologie*, June 29th, 1928, p. 256) examined the blood serum of fourteen patients with yellow fever in Senegal six of the patients were at the height of the fever when the serum was taken, and eight were convalescent or cured. A number of control serums were examined at the same time. The following spirchoetes were used as antigens: *L. icteroides*, *Sp. ictero haemorrhagiae*, *Sp. pseudo icterohaemorrhagiae*, *Sp. hebdomadis*, *Sp. autumnalis* A 1 and *Sp. autumnalis* B 1. The results were quite definite: no agglutinations, lysins, or preventive bodies were demonstrable in any of the yellow fever serums to any of the spirchoetes tested. Those results cast grave doubt on the etiological role of *L. icteroides*. A. PETTIT, G. STEFANOPOULOU, and C. AGUESSY (*Ibid.*, p. 258) record some experiments on the virus of yellow fever. Nineteen monkeys (*Macacus rhesus*) were inoculated with a strain of virus received from Sellards in West Africa. The inoculations were made subcutaneously, intraperitoneally, or into the liver. Under these conditions yellow fever developed in four to six days. At necropsy no jaundice was observed, the subcutaneous tissue was congested, the liver friable and of chocolate colour, the kidneys were congested, and the stomach contained coffee ground material. Fatty degeneration of the liver was very marked, and tubular

nephritis was apparent. A. PETTIT, G. STEFANOPOULOU, and C. KOLOCHIN (*Ibid.*, p. 260) confirm the observations of other workers on the susceptibility of *Macacus rhesus* for the virus of yellow fever, and the immunity of African monkeys to this virus. Thus five African primates—two *Cercopithecus griseo viridis*, two *Cynocephalus hamadrya*, and one *Cynocephalus papion*—proved refractory to inoculations of the virus. Working with *Macacus sinicus* they found that the immunity of this animal was variable. One after inoculation developed a mild infection and recovered, another developed a severe infection, and died in four days with characteristic lesions at necropsy.

113. The Organic Content of Human Enamel.

E. SPRAWSON and F. W. BURY (*Proc. Roy. Soc. B*, vol. 102, 1928) comment on the fact that previous analyses of enamel show many discrepancies in their results, particularly in relation to the presence of organic matter, after reviewing previous work on this subject they describe a number of tests by which they endeavoured to estimate the total carbon and nitrogen in human enamel after the removal of carbon dioxide. They considered "organic matter" as meaning compounds of carbon (other than carbonates) and nitrogen, such as are found in living tissues. The difficulties and possible sources of error in previous investigations were guarded against, with the exception of "unavoidable contamination" due to the presence of steel particles from the files used in obtaining the samples. The authors found that human enamel contains a small quantity of organic matter. The maximum amount of protein present, calculated from the highest nitrogen content, was 0.15 per cent, and from the highest carbon content 0.21 per cent, but in the latter the presence of free iron giving carbon in the "unavoidable contamination" must be taken into account. The organic content appeared to be independent of the age of the teeth or the dentition (deciduous or permanent). The high carbon/nitrogen ratio of 0.1/0.027—that is, 3.7/1 instead of 3.3/1, the usually accepted figure for protein—may be explained by the fact that the samples used for the estimation of carbon were not entirely free from iron, which contains about 1 per cent of carbon in combination. These findings confirm the work of Tomes in 1836, who stated that he found no organic matter in enamel, or not enough to amount to a weighable quantity, though he qualitatively found a trace amounting to less than 0.25 per cent.

114. Udder Infection with Streptococci of the Scarlet Fever Type.

F. S. JONES and R. B. LITTLE (*Journ. Exper. Med.*, June, 1928, pp. 945 and 957) report two cases of mastitis in cows apparently due to infection with the scarlet fever streptococcus. Attention was drawn to the first cow by the outbreak of scarlet fever in a small town, the outbreak had the usual characteristics of a milk borne epidemic. 159 of the 200 cases occurring within five days. Haemolytic streptococci were recovered from a human case of scarlet fever on the suspected farm and from a milker who just before the outbreak had visited a child with the disease. Examination of the cows on this farm revealed the presence of two with mastitis, from one of these—an animal suffering from very severe disease—a haemolytic streptococcus was recovered. After being kept in artificial culture for six months, this organism was injected into the left hind quarter of the udder of a normal cow, the dose used was one millionth of a cubic centimetre of an eighteen hour serum broth culture, and the injection was made into the teat by means of a tube. Two days later a very severe mastitis developed, which was accompanied by fever and other constitutional symptoms, and which led to atrophy of that quarter of the udder. Haemolytic streptococci were recovered from the milk in enormous numbers. The second case of natural infection of a cow with haemolytic streptococci was not accompanied by any obvious increase in the incidence of scarlet fever in the human population consuming its milk, though the conditions were apparently not suitable for determining this point exactly. A study of the two strains of streptococci recovered from the cows, together with those recovered from the throats of the two human carriers, was then undertaken, these were compared with each other, and with two stock strains of known scarlet fever origin. A non-haemolytic streptococcus of bovine origin and three strains of *Sirep. epidemicus* were included. The tests employed were the final hydrogen ion concentration in dextrose broth, the pathogenicity for rabbits, the precipitin test, and the formation of a toxin producing a reaction in a Dick positive person. To all these tests the strains from the cows responded like true scarlet fever streptococci. It would appear, therefore, that cows may suffer from a natural infection of the udder with streptococci of human scarlatinal origin.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

115. Clinical Varieties of Paroxysmal Hypertension

F. DONZETOT (*Paris Méd.*, July 7th 1928, p. 19) classifies the paroxysmal types of arterial hypertension into three groups. The first consists of those cases of paroxysmal hypertension which are grafted upon a permanent hyperplesia. Although no symptoms may be experienced, such manifestations as headache, transitory paralysis, and loss of memory, speech, sight, or hearing are not uncommon. While cerebral angiospasm accounts for these symptoms a similar arterial phenomenon affecting the peripheral and splanchnic blood vessels may cause pain and tingling in the limbs and abdominal colic. The danger of cerebral haemorrhage and of left ventricular failure depends largely upon the usual blood pressure level. The second group contains those cases in which paroxysmal hypertension is associated with a known clinical syndrome. The author quotes as illustrations of this group two cases in which mechanical irritation of the pharyngeal plexus and of the vagus nerve by new growths was related to the onset of typical paroxysmal hypertension. These instances constitute the clinical demonstration of the well known physiological result of stimulating the central end of the cut vagus nerve. The third and last group is that of essential paroxysmal hypertension, of which the literature contains but four examples. In these patients, all young adults, the blood pressure would rise abruptly in the attacks from a usual level of perhaps 130 mm. of mercury to the neighbourhood of 250 mm., and at the same time cramping, pains in the limbs or violent constricting pain in the epigastrium or thorax would be experienced. Such events as retinal haemorrhage, oedema of the lung and severe abdominal colic were related to some of the attacks, and in the three patients on whom necropsies were performed tumours were found related either to the suprarenal gland or the abdominal sympathetic ganglia.

116. The Incubation Period in Gonorrhoea.

M. A. SAIGRAJEFF and E. I. LINDE (*Derm. Woch.*, May 26th, 1928, p. 695) investigated the incubation period of 388 patients who had had one or two attacks of gonorrhoea, and found that of 270 patients who became infected with gonorrhoea for the first time 207 (76.5 per cent.) did not have a longer incubation period than four days, while one of five or more days was noted in only 63 cases (23.5 per cent.). Of 118 patients who had a second attack of gonorrhoea, 95 (80 per cent.) had an incubation period of four days, and 13 (26 per cent.) one of five days or more. There was therefore no difference in the incubation periods of first and second attacks. As regards the question of the influence of mixed infections on the duration of the incubation period, it was found that among 88 patients in whom there were other organisms besides gonococci the incubation period did not exceed four days in 63 (75 per cent.), and only in 25 cases (18.5 per cent.) was it longer. It is well known how difficult it is to obtain a pure culture of gonococci, although the greatest care is taken to avoid contamination with other micro-organisms. The conclusion derived is that if non-gonorrhoeal organisms exert any influence on the incubation period this must be quite exceptional. In three cases the incubation period was very long—namely, eighteen days in one case and forty days in two. In these cases the attack was characterized by the formation of deep infiltrations in the urethral tissue. The occurrence of relapses and reinfections did not appear to have any relation to the duration of the incubation period.

117. Agranulocytosis.

C. AUBERTIN and R. LEVY (*Arch. Mal. du Cor. des Faisanceux*, June, 1928, p. 359) have collected a number of cases of this disease recorded by various authors. Agranulocytosis is an infection which runs a rapid course, occurring usually in middle aged, apparently healthy women but occasionally found in males. Jaundice is usually present, and the disease is accompanied by necro-accrotic lesions of the mucous membranes of the cheeks and pharynx and occasionally of the genitals and anus. Blood films show a very definite leucopenia, with complete, or almost complete, disappearance of polymorphonuclear leucocytes. The disease is usually fatal, but there is an occasional recovery. One woman recovered after an illness lasting six weeks, the blood picture becoming quite normal. Two years later she had another attack of agranulocytosis, and this proved fatal in fifteen days. There is no sign of pathological changes in the

hemopoietic organs except the disappearance of polymorphonuclear leucocytes from the bone marrow. In the majority of cases there is no alteration in the number of red corpuscles nor of the blood platelets. There is no evidence of the haemorrhagic diathesis, but in a certain number of cases haemorrhages and anaemia occur. The lesions of the mucous membranes show no signs of healing. Treatment seldom arrests the rapid progress of the disease, but occasional successes have followed antitoxic and anti-infective treatment. Injections of acridine, trypanflavine, mercurochrome, and colloidal silver have been tried. In a case due apparently to streptococcal infection specific serum therapy appeared to have a favourable influence. In another case protob therapy was employed. Radiotherapy of the bone marrow, in small dosage, has been successful in four recent cases, a few hours after irradiation clinical improvement occurred, with increase in the number of leucocytes and of young granular myelocytes, further irradiation was followed by rapid recovery, but in another case of a severe septicæmic type this treatment failed, though combined with frequent transfusions of blood. In cases of pure agranulocytosis, and also in cases associated with anaemia and haemorrhage, transfusions of blood appear to have been ineffective, although theoretically they should assist the bone marrow to recover its functions and increase the patient's resistance to the toxic infective process, especially when transfusion is combined with radiotherapy. In the treatment of the necro-accrotic lesions local application of mild antiseptics is recommended. Arsenobenzenes have been used with success in certain forms of agranulocytosis. It is advised that they should be prescribed as routine treatment in all cases. The authors refer to several cases of syphilis in both sexes in which agranulocytosis followed arsenobenzol treatment. Only one of these patients, a woman aged 22 recovered. After the fourth injection of arsenobenzol she had moderate fever, bucco-pharyngeal lesions, and haemorrhages. The blood showed extreme anaemia, and the leucocyte count was only 2,800, with absence of polymorphonuclears.

118. Encephalitis in Paratyphoid B Infection.

G. TH. WAIT (*Monatsschr. f. Kinderheilk.*, June, 1928, p. 271) records a case of paratyphoid B fever in an infant, aged 11 months, in whom the diagnosis was confirmed by the presence of the organism in the blood and stools and a positive Widal reaction. The disease commenced suddenly with high fever and convulsions. Lumbar puncture was performed and the convulsions ceased, but right hemiplegia developed. The cerebro-spinal fluid apart from hypertension was normal. Almost complete recovery followed.

Surgery.

119. Carcinoma of the Rectum.

L. J. HIRSCHMAN and M. S. ROSENBLATT (*Journ. Amer. Med. Assoc.*, May 26th, 1928, p. 1697) report an early case of colloid carcinoma of the rectum which emphasizes the importance of sending all tissue for laboratory diagnosis regardless of how innocuous it may appear to the naked eye. A man, aged 47, had noticed for seventeen years a reducible protrusion from the rectum on defaecation which was frequently accompanied by haemorrhage. For the last three years he had not been able to reduce the prolapse, from which there had been considerable mucous discharge. There was nothing in his past history or present condition pointing to malignancy. Three tumour masses present were removed with a wide margin of tissue. These were sent as a matter of routine for examination and showed colloid carcinoma. Convalescence was uneventful, and the patient was given vigorous X-ray after treatment over the pelvis and abdomen with radium at the site of the lesion. The case appeared to be a very early one, as there was no ulceration of the mucosa, the lumen of the rectum was not constricted, there was no affection of the general health or blood count, and there were no signs of any metastases. The prognosis is considered good owing to the early and wide removal and the subsequent radium and X-ray therapy. The authors emphasize the point that despite the careful examination the diagnosis of carcinoma was only made in the laboratory. Since at the operation it appeared to be a clear case of prolapsing thrombotic haemorrhoids they might have been tempted to discard the tissues without such examination thus showing the importance of submitting every case to laboratory diagnosis.

120 Congenital Cystic Kidneys.

R J WILLAN (*Newcastle Med Journ* April, 1928, p 117) records an analysis drawn from personal observation of 22 cases of congenital cystic or polycystic kidneys, 15 occurred between the ages of 30 and 49, and 13 of the patients were females. He states that the kidney may attain an enormous size, one recorded case weighing 16 lb., while the condition in a foetus has been known to obstruct labour. The disease is bilateral though usually more advanced on the left side, and in every instance there was a palpable tumour in one or both flanks. Macroscopically the appearance is that of a semisolid bunch of grapes, the individual cysts of which do not communicate with each other, nor with the hollow portion of the kidney, they contain a clear albuminous non-urinary fluid, and it is usually impossible to detect any normal renal tissue. Microscopically the cysts are lined with flattened epithelium, a surprising amount of renal secreting tissue being seen between them. Usually symptoms are absent until early middle life, but when they arise they are those of a chronic interstitial nephritis with later uraemic manifestations. Pain may be absent, but in 6 there were attacks of acute renal colic, one without any haematuria, and the other 5 without visible clots. None of the patients with clot retention had acute renal colic, showing that the colic was not due to a clot passing down the ureter. In 12 there was no haematuria. The chief physical sign is the presence in each flank of a well defined tuberoso tumour of firm consistence and moving on respiration. A double pyelogram showing the normal hollow portions of the kidney elongated vertically and to a lesser degree horizontally, definitely establishes the diagnosis and the treatment is entirely diietetic. In urgent haematuria he advises the free use of Contrexéville water haemopoietic injections washing out the pelvis of the kidney through a ureteral catheter with 1 in 10,000 hot silver nitrate solution, and finally blood transfusion.

121 Subluxations of the Vertebral Column

GOURDON (*Journ de Med de Bordeaux et du Sud Ouest*, June 25th 1928, p 501) believes that vertebral displacements are much more frequent than is supposed and that they are the cause of a great number of vertebral and paravertebral pains to which various terms have been applied. These subluxations are due to some mechanical cause such as a blow, fall, or violent muscular contraction and are most often situated in the more mobile regions of the column—namely, the cervical and lumbar. The condition caused by an antero-posterior or lateral gliding of the vertebra, or a combination of both, occurs immediately after the traumatism. The symptoms, which sometimes come on rapidly, sometimes very slowly, are always the same: functional trouble, projection of one or, more rarely, two spinous apophyses, and pains radiating into the shoulders, arms, or lower limbs. An erroneous diagnosis of Pott's disease is generally made, though the symptoms of this are entirely different. In subluxations the spine is not completely immobilized by the muscular contraction, the pain is not intense on pressure, patients show no need of supporting the head or of walking carefully to avoid the least obstacle and the neck is not shortened but rather elongated, the lordosis being straightened and sometimes even changed into kyphosis. Radiographs of Pott's disease show a settling of the affected vertebral bodies and effacement of the intervertebral discs while those of subluxations reveal a spinal integrity with a rapprochement of the spinous apophyses. According to Still the troubles noted in these conditions are due to the repercession of the vertebral displacement on the immediately adjoining tissues, particularly the ligaments and muscles, which tend to contract and become painful. Old subluxations may cause slight compression of the nerve roots. Vertebral subluxations respond readily, with an immediate cessation of all symptoms, to orthopaedic treatment. Gourdon describes three cases of cervical and one of dorsal subluxation thus treated, and refers to several cases of dorsal and lumbar subluxations reported by Lavezzi.

122 Mixed Tumours of the Thyroid Gland

A L. HERTZLER (*Arch of Surg* June 1928, p 1187) regards the so-called adenoma of the thyroid gland as a mixed tumour which is rather a true neoplasm than a goitre. It is comprised of acinar more or less characteristic of immature thyroid tissue. It is of slow growth, and although benign in the early stages may undergo unaided degeneration or become malignant. Sometimes the acini develop colloid and lead to toxicity but this is of a mild degree. It may occur in young persons usually in the absence of enlargement of the gland proper. It is generally solitary, ovoid in shape, and firm to the touch unless degeneration has occurred when it may be soft or fluctuant. As these tumours are unaffected by medical

treatment, their removal by surgical means is advisable owing to the danger of malignancy developing in later years, or haemorrhage into their substance causing the death of the patient. The toxicity of a mixed tumour never reaches the degree of a true exophthalmic goitre and eye signs are never produced. Permanent cure follows removal if effected before the invasion of the capsule.

Therapeutics

123 Prophylaxis of Rabies.

M J ROSENAU (*New England Journ Med*, May 31st 1928, p 787) discusses recent improvements in the treatment of wounds with reference to the prevention of rabies. While cauterization of the wound and the Pasteur prophylactic treatment afford efficient measures for the individual, Rosenau believes that the best method of controlling and preventing the disease is the compulsory impounding of all stray dogs and the supervision of licensed dogs. He adds that all parts of a suspected wound, including pockets, recesses and the edges of the skin should be thoroughly cauterized with a glass rod dipped in strong nitric acid. The incubation period ranges from fourteen days to a year or more, with an average of forty days the length depending upon the virulence of the virus and the site of the wound, the most dangerous regions being those having a rich nerve supply. Prophylactic treatment by the Semple method is rapidly becoming the method of choice on account of its simplicity and the relative infrequency of paralytic complications. The material for injection is prepared from fresh fixed virus in the brain, medulla, and spinal cord of rabbits, ground up in sterile salt solution containing 1 per cent carbolic acid, which kills the virus after being kept at 37°C for twenty-four hours. Further dilution follows with equal parts of sterile normal saline solution so that the preparation finally contains 4 per cent of the dead virus in 0.5 per cent carbolic acid normal saline solution. 2.5 c.c. of this is injected subcutaneously in the abdominal wall once daily for fourteen days. Rosenau adds that treatment should be commenced at once when the dog is known to be mad or shows suggestive symptoms. It being only allowable to await diagnosis when prompt laboratory facilities are available. After exposure to infection from being licked by a rabid dog or from washing the mouth of a rabid horse protective treatment should be advised since it has been shown to be possible to infect animals by rubbing the virus on the shaved skin.

124 Oleothorax in Pulmonary Gangrene.

T LUCHERINI (*Il Politecnico*, Ser Prat. May 7th, 1928 p 643) discusses the induction of collapse in a gangrenous lung by introducing oil into the pleural cavity. Oleothorax has been stated to be useful in bacillary pleural effusions, with or without secondary infections and is employed to bring about the collapse of loci resistant to the action of gaseous pressure. It acts mechanically, persistently compressing the lung while maintaining freedom of movement of the pleural surfaces. Bernou concluded that since the injection of air had to be so frequently repeated for the purpose of maintaining collapse of the lung it was better to employ oil. A vegetable oil is usually recommended although kerosene prefers pure paraffin oil which is strictly neutral, practically anhydrous and of high viscosity. In either case it is usual to add some antiseptic in weak solution preferably gomenol from 2 to 4 per cent on account of its balsamic action in lung disease. Villaret and others have obtained good results by using an oil subjected to irradiation with ultra violet rays, employing as much as 500 mg., but never more than 600 to 650 c.c. Lucherini has taken the opportunity of treating four female patients all aged about 20, with pulmonary gangrene on the side for the purpose of comparison. In two collapse was brought about by air and in the other two by oil. All presented much the same symptomatic and clinical characters and none had any pleural or general complications. The purest olive oil was used, sterilized, with the addition of 3 per cent gomenol and it was introduced by means of a large syringe graduated to 100 c.c. into the fourth intercostal space in the anterior axillary line. To control the intrapleural pressure during the introduction of the oil a second puncture was made in the intercostal space above. This second needle was attached to a manometer. Before the oil was introduced about 50 c.c. of air was admitted so as to avoid injecting oil into the parenchyma of the lung. Not more than 75 c.c. of oil was introduced at a time. It was warmed to 100°F. This was given three times at intervals of twenty-four hours for three days and after three days cessation the procedure was repeated. After seven days three more injections, each of 50 c.c., were given at intervals

of four days. In the first patient the expectoration diminished at first and also the fever, but she did not improve, there were always cough and fever and sometimes haemoptysis and vomiting. She continually grew worse, and died two months after admission. The second patient was treated similarly, the expectoration and the fever diminished, but she also did not improve. The irritating cough and fever continued with occasional haemoptysis, and she died within six weeks of admission. The first of the two patients treated by pneumothorax for the purpose of comparison received 450 c.c. of air and continued to improve steadily until discharged from hospital two and a half months later, she was in very good health two months afterwards. The fourth patient was treated by pneumothorax, she also steadily improved, and was discharged completely cured. Luchner, who supplies radiographs of these cases, concludes that the frequent repetitions necessary to maintain a pneumothorax are not to be considered in view of its relative success, and that the use of oil instead of air is both clumsy and unjustifiable.

123. Whey as a Therapeutic Agent.

M. RILAUD (*Bull. Soc. Méd. des Hôp. de Paris*, May 24th, 1928, p. 801) draws a distinction between milk as a food and milk as a medication, and points out that its therapeutic value lies in the serum. Eliminating the casein and fats, he uses the whey, having determined experimentally that this is an excellent cholagogue and diuretic. Illustrations in colour are supplied of fluid withdrawn from the stomach before and after administration to demonstrate the increased flow of bile. He also gives tables indicating the diuretic and eliminative effect on the kidney, both healthy and diseased, as compared with pure water. Not only is there an increase in the volume of urine passed, but it is also more concentrated, especially in diuretic kidney. As compared with milk the whey was found to be less effective.

Disease in Childhood.

126. Tonsillar Hypertrophy in School Children

P. HERTZ (*Acta Paediatrica*, Supplement April 29th, 1928, p. 97) examined 1,185 children 639 of whom were boys and 546 girls, in two schools at Copenhagen shortly after admission, and found that 134 had hypertrophy of both tonsils, 9 hypertrophy of the left tonsil only, and 8 of the right only. The frequency of hypertrophy—roughly 13 per cent. of all the children—was about the same among the boys as among the girls. Most of the children were 6 or 7 years old, and very few were over 8 years of age. Subsequent examination showed that in 34—that is in nearly 25 per cent. of the tonsillar hypertrophy entirely disappeared in the course of a year. In some and in others somewhat later, while it was obviously diminished in 17 others. During the period of investigation tonsillectomy or tonsillotomy was performed on 21 children. Hertz found that most children with tonsillar hypertrophy which remained unchanged many years were not inferior to other children either bodily or mentally, and did not seem to be more susceptible to disease than others.

127. Infantile Epilepsy

R. DUPRE (*Gaz. Hebdomadaire de Bordeaux*, June 3rd, 1928, p. 3-6) reports a case of infantile epilepsy which showed no improvement from medical treatment but responded markedly to a ketogenic diet. The patient, a boy aged 5, suffered from convulsive fits which were ushered in by precursory sensations, and caused collapse and loss of consciousness. Sometimes all the limbs and the face sometimes only one or two members, were the seat of convulsive movements. During the fits a little froth appeared on the lips, but there was no biting of the tongue or evacuation of urine. The following symptoms also were absent: hydrocephalus, hereditary syphilitic stigmata, exaggeration of the reflexes and clonus of the feet and patellar Babinski's sign, paresis and contracture of the limbs, paralysis of the cranial nerves and ocular troubles. The gait was not affected and in the intervals between the seizures the patient was normal though psychological disturbances of ebullient and turbulence were exhibited. The seizures lasted for about five minutes, and their frequency increased from one to three or four per hour. They occurred during both the night and day. The cerebrospinal fluid was normal, though the Wassermann reaction was doubtful in both the child and parents. Specific treatment with mercuric iodides combined with epileptic therapy first with bromides and then with gardenal had no appreciable effect though the doses of the latter were increased. Finally a diet was instituted consisting of meats, fish and fatty foods with a minimum of bread, starches, vegetables and fruits. At first medical treatment was continued, but was

abandoned in a month. After three months' dieting the fits ceased and the physical and psychological condition also greatly improved. The diet was well tolerated, only a slight ketosis was produced, as evidenced by more traces of acetone in the urine. Dupré reviews the work of American investigators, most of whom claim that only essential infantile epilepsy, and not the symptomatic or adult type, will benefit from this treatment—a view with which the author does not agree. Various theories are held as to the action of a ketogenic diet in epilepsy. Helmholz believes that it causes a metabolic alkalosis of the fats, and Wilder that the diacetic acid exerts an anesthetic effect on the nervous system. Bliss's theory is most generally held, that the crises occur when there is a tendency in the blood to alkalosis. No accidents have been reported from the use of this treatment, and the only contraindications are intestinal cases with hepatic or pancreatic deficiency.

123. Broncho pneumonia in Infancy

FOLLOWING a recent experience of 50 cases of broncho-pneumonia in infancy, A. BOCCINI (*La Pediatria*, May 15th, 1928, p. 507) reviews Nassan's classification of this condition into six types—namely, the simple pulmonary, cardio-vascular, atonic, alimentary, meningitic-cerebral, and the septic. While not accepting this classification as indicating separate types, but rather as defining cases in which there is greater or less predominance of various symptoms, he has adopted, with good results, Nassan's therapeutic suggestions for each type. In the simple pulmonary type he trusts mainly to fresh air and sedatives such as urethane. In the cardio-vascular type he has found much benefit from the use of glucose injection coupled with adrenalin. In the meningitic type lumbar puncture frequently repeated often does much good, while calming measures such as warm baths and the administration of chloral or sulphate of magnesium are useful. In the grave toxic type often fatal in thirty-six hours, no treatment seemed to be of much avail. Where a large extent of lung was involved with much dyspnoea, a free use of oxygen was indicated. Poultices were found to be of doubtful value.

129. The Heart in the Normal Child

EDITH M. LINCOLN and R. SPILLMAN (*Amer. Journ. Dis. Child.*, May, 1928, p. 731) have found that normal hearts in children fall naturally into four groups which correspond exactly to the four types of adult hearts described by Hirsch and Shapiro. These writers described a type of heart which is characteristic of each one of the four main types of body build—the short, broad heart of the person with a hypersthenic habitus, the long thin heart of the person with an asthenic habitus, the true 'drop' heart of the person with a hyposthenic habitus, and—the most common type of all—that belonging to the person with a sthenic habitus. The types of hearts in children, however, do not bear a constant relation to the type of body build. Changes from one type to another are uncommon. Until the age of 7 the girls' hearts are smaller than the boys', but after 11 this condition is reversed. There is a closer correlation between height and the size of the heart than between age and the size of the heart. Approximately one third of the heart lies to the right of the mid line in children from 4 to 13 years of age. The transverse diameter of the heart is approximately one half of the width of the chest in children from 2 to 13 years of age, and there is no change in this relation with increasing age or height.

Obstetrics and Gynaecology.

130. Pelvic Tuberculosis in Women

SANTY (*La Gynécologie*, June 1928, p. 354) recommends the combination of surgery and heliotherapy at high altitudes in generalized or localized tuberculous peritonitis in women. He advises that preliminary exploratory laparotomy should be performed with or without evacuation of effusion, and the ablation of easily operable lesions. In some cases it is necessary, after a course of heliotherapy, to perform a second operation on residual lesions. He describes six cases in which success was thus obtained. One woman aged 30, who had borne two children had suffered for three months from abdominal swelling, rapid emaciation, and a nocturnal temperature of 102°F. She was cachectic, with distended abdomen and a large kidney like tumour in the left hypochondrium, another tumour in the left iliac fossa extended downwards into the pelvis. Both tumours were encysted collections of peritoneal exudate. Laparotomy showed all the viscera studded with small yellowish tumours, causing numerous adhesions of the small intestine. The ascitic fluid was evacuated and a tuberculous ovary removed. A month

lateral abdominal heliotherapy was proscribed and caused progressive improvement. Eight months later the abdomen was soft, but the Fallopian tubes remained enlarged and hard. Two years later the improvement was still maintained, but subsequently the temperature rose to 101.3°, and the tubes were painful and fluctuating. A second laparotomy showed that all the tubercles had disappeared, but the pelvis was looked by adhesions between coils of small intestine and the tubes. Total hysterectomy resulted in complete relief. Another woman, aged 25, had pelvic peritonitis in 1923. Eleven months later the left ovary and tube were inflamed; removal of the ovary was followed by improvement. Nine months afterwards her temperature rose to 102.2°F, and laparotomy disclosed a generalized tuberculous peritonitis, the tube being removed with difficulty. The patient had a subsequent attack of pleurisy necessitating an intensive course of heliotherapy at a high altitude in 1925, but regained good health. Santy believes that tuberculous lesions of serous membranes react well to heliotherapy.

131 Sarcoma of the Vulva.

H. S. MORGAN (*Amer. Journ. Obstet. and Gynecol.*, June, 1928, p. 861) records in detail a case of unpigmented sarcoma of the vulva occurring in a girl aged 16. This type being rare, sarcoma of the vulva is a very malignant, rapidly growing tumour with early metastasis to distant organs, the melanotic form being much more malignant, and metastasizing much earlier than the unpigmented. The tumours are usually composed of polymorphous cells, varying in type from spindle to round. Sarcoma of the vulva is usually fatal; early diagnosis and excision followed by intensive x-ray treatment offer the patient the best chance. All growths about the vulva, particularly fibromas and hard tumours in the region of the Bartholin glands, should be removed immediately to eliminate the danger of sarcomatous degeneration.

12. Hysterectomy in Uterine Inversion

FOR the operative treatment of uterine inversion U. STAMATOPOULOS (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, June, 1928, p. 558) advocates a method combining abdominal with vaginal hysterectomy. A partial (fundal) hysterectomy is performed abdominally at the constriction of the invagination, and the uterus, probably infected, is extracted per vaginam, closing of the cervix and peritonization being secured as in subtotal hysterectomy. Many advantages are claimed for this method. It is said to be (1) rapid, (2) always easy, (3) without danger, since the site of the incision is far from the ureters and bladder, (4) aseptic, since the infected uterus is not handled, and thus a septic operation is converted into an aseptic one, and (5) it is not a blind procedure. It can be employed with advantage in recent inversions, in chronic cases with peritubal adhesions, and in inversions complicated by submucous tumours of the fundus. Spinal anaesthesia, when not contraindicated by anaemia or hypotension, will prove advantageous. The author contrasts this procedure with the usual operative measures. Total abdominal hysterectomy involves danger of infection by removal of the infected uterus abdominally and of injury to the ureters. It occupies more time and leaves the vaginal wound open, thus prolonging post-operative treatment. Subtotal hysterectomy after abdominal reduction without colpo-hysterectomy is applicable only in cases of recent inversion where reduction is easy. It may cause fatal syncope during reduction, and it exposes patients to the same risks as does total hysterectomy. Vaginal hysterectomy is not always easy, even in recent inversions; it is a blind method and consequently dangerous, and it is septic. Moreover, it cannot be employed in cases where the invaginated constriction lies high and is fixed by endo-perimetritic adhesions. A case is described in which this operation was performed for a complete inversion immediately following delivery.

133. Treatment of Tuberculosis of the Uterine Appendages and Peritoneum

T. KELLER (*Gynecol. et Obstet.*, April, 1928, p. 286) reports the results obtained in 69 cases of tuberculosis of the adnexa, 37 being associated with tuberculous peritonitis (53.6 per cent.), and 47 cases of tuberculous peritonitis not associated with disease of the uterine appendages. He recommends that in cases diagnosed as genital tuberculosis x-rays should be employed. When the diagnosis is uncertain and only established after operation, post-operative irradiation will assist in the cure. In chronic exudative tuberculous peritonitis, especially with much ascites, laparotomy is indicated, a solution of colloidal silver with methylene blue is introduced into the abdominal cavity, and it is possible that very small doses of radiation afterwards applied to the abdomen have an enhanced effect due to secondary radiation of the metal over the whole surface of the peritoneum.

Pathology.

135 Reducing Powers of the Tissues in Tuberculosis.

FERRLEIRA DE MIRA (*C. R. Soc. de Biologie*, June 1st, 1928, p. 1611) estimated the reducing powers of the tissues of guinea pigs by means of an inditobenzol. This substance in the oxidized state is white and insoluble in water, in the reduced state it is yellow and is soluble in water. The muscle and the liver were finely divided, and 1 gram was added to a tube containing 10 c.c. of distilled water and 0.4 gram of the powdered indicator. After twenty-four hours at room temperature the mixture was filtered, and the colour of the indicator was estimated in a Duboseq's apparatus. Taking the reducing power of the tissues of the normal guinea pig as 100, it was found that in generalized tuberculosis this figure was reduced to between 80 and 90 as a rule in the early stages of the disease when only the focal glands were affected, the reducing power of the tissues was about normal.

135 Serum Proteins in Epilepsy

In a series of 136 epileptic patients F. FRISCH (*Wien. klin. Woch.*, June 14th, 1928, p. 838) found that the average serum protein content was considerably higher than that recorded for 147 other persons chosen at random. Thus 76 per cent. of the epileptics showed a protein value of 8 to 9 per cent. and only 1.4 per cent. had less than 7 per cent., while in 59 per cent. of the controls the percentage of serum proteins was less than 7, and in 7.4 per cent. of them it was 8 to 9. It was also found that in the pre-paroxysmal phase there was generally a relative increase in albumin, while in the post-paroxysmal phase the proportion of globulin was raised. Various investigators have reported in certain acute febrile conditions such as pneumonia, typhoid fever, and the exanthemata, which are associated with a relative or absolute increase in globulin, that the epileptic fits cease during the febrile attack. It has also been shown that there is an alteration in protein metabolism with diminished excretion of nitrogen, especially in the pre-paroxysmal phases of epilepsy. The suggestion has been made that this is due to a lowered metabolism in the cells which increases their irritability to whatever stimulus initiates the fit. In dogs, when the globulin was increased by injections of ichn or by starvation, fits were less readily induced by faradic stimulation through a trephine opening than previously or as compared with controls. Attempts to produce artificially an increase in globulin in human subjects by injecting various antigens were not always successful. It was found, however, that in those cases of epilepsy in which it was possible to increase the proportion of globulin to albumin—as, for example, by the injection of diphtheria toxin—a marked effect on the incidence of fits resulted. One patient who had suffered from fits for ten years, and had had about ten in the previous three months, received ten injections of diphtheria toxin between November 21st, 1927, and January 17th, 1928, which resulted in febrile reactions and painful swelling at the point of injection. He remained free from fits from November 27th to February 10th. On the other hand, in a number of cases in which treatment produced no effect on the serum proteins it also had no effect on the fits. Frisch suggests that various operations advocated from time to time—inflammatory reactions and even the old-fashioned seton—probably produce their effect by a non-specific increase in the globulin content of the blood, though the mechanism by which this is brought about is still unknown. Though these results suggest an etiological line of treatment he gives the warning that the methods at present available for increasing the proportion of globulin have the disadvantage that during the reactionary phase albumin is again increased.

135. Immunity to Diphtheria in Measles.

In order to determine whether measles reduces the immunity to diphtheria G. RAYMOND and C. ZOLLER (*C. R. Soc. de Biologie*, March 9th, 1928, p. 679) estimated the antitoxin in the blood on the first day of the eruption, and on the same day gave the patient an injection of 0.5 c.c. of diphtheria antitoxin. Ten days later the antitoxin titre was estimated again. In ten patients examined it was found that the titre rose from one tenth to one third of a unit after injection of antitoxin, as would occur in a healthy subject. In case the difference in the two titres should be due to a fall in the antitoxin value during the febrile stage, followed by a return to a higher figure, two successive estimates with an interval of ten days between them were made on another series of ten subjects without giving them an injection of antitoxin, and it was found that no change occurred in the antitoxin titre. The rise in the first series was therefore due to stimulation by the antitoxin injected.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

137 Symptomatic Facial Neuralgia due to Dental Caries

CAVATTE (*Gaz. Hebdomadaire de Bordeaux*, June 10th, 1928, p. 370) relates the case of a man, aged 43, first seen by him in April, 1928, complaining of facial pain occurring every night. Since August, 1927, violent crises of pain began about 7 p.m. and lasted fifteen to twenty minutes beginning at the external auditory meatus and extending along the course of the inferior maxillary nerve to the lower incisor teeth on the right side, the pain passed to the corresponding teeth of the upper jaw and returned to the ear, being followed by a dull ache, lasting all night and preventing sleep. A previous radiological examination had revealed no abnormality, and extract of opium had been found to prevent the attacks, though they recurred at once on its withdrawal. At the examination of the patient in April, 1928, no abnormality of skin sensation on the right side of the face was found, and there was no tenderness on pressure over the bony foramina of the fifth nerve. Caries of the neck of the second lower molar on the right side was noted, associated with a vestibular gingival fistula. There was no pain on probing the carious part of the tooth, but pain was produced by vertical pressure on the crown. An x-ray examination showed the presence of root sepsis, and removal of the tooth, followed by extraction of the socket, brought almost immediate cessation of pain. This case is considered noteworthy because of the absence of pain over "pressure points", the complete control of pain by opium, without increasing doses, the mixed nature of the pain—paroxysmal and continued, and the fact that cases of symptomatic neuralgia are frequently thought to be of idiopathic origin for lack of systematic search for a focus of irritation.

133. Subacute Interstitial Tuberculous Myocarditis

ACCORDING to L. GALLAVARDIN and L. GRAVIER (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, July, 1928, p. 472) it is exceptional to find subacute interstitial myocarditis in young subjects who have died from progressive cardiac failure, and still more unusual to discover that the lesions are tuberculous. They report the case of a man, aged 33, who had been discharged from the army eleven years previously on account of bronchitis and haemoptysis, and, during the last seven years of life, had had numerous attacks of peritonitis. At the autopsy the dominant lesion was an extensive subacute myocarditis, chiefly involving the lower half of the left ventricular wall, with extensive confluent fibrous plaques, visible to the naked eye. There was no vascular or valvular lesion. A healed tuberculous scar was found at the apex of the left lung, and there were extensive peritoneal adhesions. The authors have collected the records of several previous cases, the ages of the patients ranging from 25 to 35. They remark that it would be useless to describe the symptoms, for this variety of subacute myocarditis cannot be distinguished from other forms due to different causes. The comparative youth of the patients permits elimination of many other causes of myocarditis, usually found in later life. The authors add that the possibility of this form of myocarditis must be borne in mind in the case of a young patient who is suffering from progressive cardiac failure without evidence of vascular or valvular lesion.

139 Fever in Gastric and Duodenal Ulcer

S. BANG (*Arch. Int. Med.*, June, 1928, p. 808), in his investigation of pyrexia in peptic ulcers, shows that this symptom is by no means uncommon. His observations are based upon 358 cases diagnosed as ulcer and suffering from no other disease. Of these cases 50 per cent showed elevations of temperature lasting several days, the high percentage in this series as compared with those of other workers being due to the relatively more acute lesions in the former group. Among the 138 cases in which manifest haemorrhage occurred fever was present in 90 per cent, those patients having principally acute ulcers or acute exacerbations of old ulcers. Anaemia is discounted as the cause of fever since it may persist long after the temperature has become normal, even if it was originally elevated and may also be present in severe degree without any pyrexia. The possibility of absorption or decomposition of blood in the bowel giving rise to fever is discussed, and it is shown that this symptom is generally delayed one to four days from the onset of oesophageal haemorrhage, while it is not uncommonly absent after severe bleeding from

gastric ulcer. Further evidence of the independence of temperature and blood absorption is the demonstration of thirteen cases showing fever but complete absence of blooding. In his search for the cause of pyrexia the author turns to the pathological material obtained at gastrocotomy operations by other observers. Their researches showed that marked inflammatory reaction of the mucous membrane surrounding the ulcer is demonstrable in most fresh specimens. Microscopic examination of such inflamed areas reveals small haemorrhagic erosions, oedema, and perivascular infiltration of leucocytes, it is considered that such gastritis is the probable cause of any fever present. That this pathological change in the mucous membrane is the precursor of the typical ulcer is suggested by its presence in certain cases in which operations were performed for gastric or duodenal ulcers and neither of these conditions was found.

140 Autonomous Typhoid Cholecystitis.

I. NOZARI (*Thèse de Paris*, 1928, No. 130) discusses the important part played in the dissemination of the disease by masked typhoid infections, as illustrated by localization of the typhoid bacillus in the gall bladder, he collected eleven cases in patients aged from 13 to 60. The cholecystitis, which may be catarrhal but is more frequently suppurative, is accompanied by considerable constitutional disturbance, though there is no true typhoid state or any sign of typhoid fever. The diagnosis can be made by laboratory methods only. Blood cultures rarely give any help, but the Widal reaction is always positive. The diagnosis is established by direct culture of the bile or by duodenal intubation. Although the bile forms an excellent culture medium for typhoid bacilli, and therefore plays an important part in the persistence of the organisms, the author is opposed to the view that latent or manifest infection of the gall bladder predisposes to cholecystitis, as most authorities have maintained.

Surgery.

141 Arterial Resection in Obliterating Arteritis.

P. STRICKER (*Rev. de Chir.*, No. 3, 1928, p. 214) divides chronic arteritis into two distinct anatomical groups: scleroses, characterized by an alteration in the vascular walls on which thrombi can be secondarily engendered, and chronic juvenile forms in which the chief factor is a primary thrombosis without any important change in the artery itself. The former group includes diabetic and syphilitic scleroses, a form described by Mönckeberg in which the calcification is confined to the media and is noted chiefly in the arteries of the extremities, and obliterating arteritis following repeated traumatism. The pathology of these various forms is discussed. Stricker believes that many different diseases can cause the same sclerosis and degeneration in an artery as in other organs, and an anatomical classification is difficult. This is true also of the second group, and though the thrombus is the primary agent, secondary changes in the arterial walls supervene so rapidly that it is often impossible to state whether these occurred prior or subsequent to the thrombosis. Two problems present themselves in considering the treatment of obliterating arteritis—namely, its pathogeny, and the localization and extent of the lesion. In diabetic and syphilitic arteritis the etiological diagnosis and treatment are evident. In the vast majority of cases however, the etiology is not clear, and, while waiting for diagnosis some efficacious and yet more conservative treatment than amputation should be instituted. Stricker divides these cases into two groups: those in which the arteritis is generalized in more than one limb, and those in which from various local causes, such as traumatism, compression, or limited frost bite, it is localized in one member. Leriche has shown that in generalized cases local surgical measures (sympathectomy and arterial resection) are useless, but that great benefit results from their use in localized conditions. He has also demonstrated that arterial resection, which in reality is a sympathectomy, is followed by a vaso dilatation, and that excision of an obliterated arterial cord causes a cessation of the vasomotor and trophic troubles due to a periarterial sympathetic lesion. Stricker advocates an extensive resection in which the whole obliterated portion of the artery is excised to a point where the thrombosis no longer exists, and where sclerosed is replaced by healthy tissue. Such treatment has given surprising results in cases of localized

juvenile and presenile arteritis, and amputation should be avoided if possible. In such cases are reported, and also three cases illustrating the inefficacy of this procedure in scule subjects.

142 Differential Diagnosis of Acute Appendicitis and Epididymitis.

J. BAUMANN (*Med. Welt*, June 9th, 1928, p. 872) describes two cases of acute epididymitis in which an erroneous diagnosis of appendicitis had been made. The first patient was a powerfully built young man who was sent to hospital for immediate operation for acute appendicitis. On admission his temperature was 105.4°F. The patient said that the pain was not increasing and there was no abdominal tenderness or rigidity on pressure. On further examination the right side of the scrotum was very red and the right testis was swollen to the size of a goose's egg, there was a copious purulent urethral discharge and the condition was evidently severe gonorrhoeal epididymitis. The second patient was a healthy looking young man who had complained, since the previous evening, of increasing pain in the right hypochondrium. Vomiting was absent and the temperature was 102.2°F. In the appendix region there was tenderness on pressure, especially immediately below McBurney's point, with muscular rigidity. The patient was prepared for operation, when a swelling of the right testis was discovered, he had been treated, four weeks previously, for gonorrhoeal urethritis, and he still had a profuse discharge. The epididymis and testis were swollen to the size of a hen's egg. Next day the temperature was normal, and there was a definite leucocytosis. The epididymitis subsided rapidly, but the abdominal pain and subhepatic tenderness persisted for four days. The spermatic cord was not tender or swollen. The author refers to four previous cases recorded, in which the differential diagnosis of appendicitis or epididymitis was difficult. In two of these the spermatic cord was more or less inflamed, swollen, and painful. In Baumann's cases the spermatic cord was not involved, although the abdominal symptoms were very definite. It is probable that these were due to lymphangitis and lymphadenitis in the portal fissure. In another case a small malignant tumour of the testis was followed by extensive metastases in the retroperitoneal lymph glands, leading to an erroneous diagnosis of gastric carcinoma. In many pelvic diseases, such as salpingitis, oophoritis, and parametritis, tenderness in the region of the portal vein may give rise to an erroneous diagnosis of cholecystitis. In contrast with these cases of epididymitis with abdominal symptoms Baumann mentions that cases of appendicitis have occurred in which pain was referred to the genital organs, with increased cremaster reflex and swelling and tenderness of the right spermatic cord, he adds that these manifestations are due to local oedema and peritonitis involving the spermatic cord.

143. Prostatism without Prostatic Hypertrophy

P. S. ROSENBLUM (*Urol. and Cut. Rev.*, June, 1928, p. 376), who records two illustrative cases, states that patients who present symptoms of prostatism do not always have hypertrophy of the prostate. Cystoscopy has shown that the following lesions may produce these symptoms—namely median bar, hypertrophy of the trigone, diverticula, which are usually situated near the urethral orifices, and sometimes at the vertex, stone in the bladder, chronic prostatitis, and urethral stricture. Cystoscopy is a valuable aid in discovering the cause for the persistence of symptoms after prostatectomy, such as a tag of tissue left attached to the internal urethral orifice, a urethral polyp developing in the prostatic bed, incomplete removal of the prostatic adenoma, the formation of a nodule in the prostatic cavity, and occasionally the prostatic urethra growing together and becoming finally closed. Post-operative prostatism can usually be avoided by careful pre-operative diagnosis, attention to the technique of enucleation, and post-operative care.

Therapeutics

144 Cardiac Therapy in Pneumonia.

In view of the frequent occurrence of cardiac failure in pneumonia E. E. CORNWALL (*Med. Journ. and Record*, June 20th, 1928, p. 637) emphasizes the importance of protecting the heart against overstrain and mechanical, nervous and toxæmic disturbances. Rest, if possible in the horizontal position, should be maintained from the onset of the disease until at least a week after defervescence. In cases of cardiac weakness or organic disease this period should be prolonged. The patient should be permitted to roll over in the most comfortable position. In cases of severe cardiac dyspnoea some elevation of the head and chest may be required. Bradycardia necessitates strict rest in the

horizontal position. The alimentary system requires attention, since mechanical pressure from tympanites, dilatation of the splanchnic blood vessels, reflex vagal stimulation, and intestinal toxæmia may cause danger. Purgation is to be avoided, since moderate constipation is less dangerous to the heart than the routine artificial induction of evacuation of the bowels. Morphine as an anodyne and nerve sedative is often useful in restlessness and insomnia, caffeine is a respiratory and vasomotor stimulant. Cornwall prefers atropine to any other direct heart stimulant, he gives it on the first appearance of symptoms of myocardial failure in carefully graduated amounts, since large doses may exhaust the heart in the early stages of the disease. He starts with 1/1000 grain every four hours, increasing if necessary to 1/500 grain doses, and rarely to 1/250 grain. The effect is carefully watched, and the dose reduced or the drug discontinued at the earliest possible moment. It should not be given as a rule by the mouth, but by hypodermic or intramuscular injection. The author believes that the daily administration of 30 grains of calcium chloride or lactate acts as a direct heart stimulant. He also uses strychnine, caffeine, morphine, and alcohol as heart regulators, he considers that digitalis might be indicated in cases complicated by arrhythmic fibrillation, but he has seldom found it was required. Strychnine is given early when the blood pressure is unduly low. Alcohol is a cerebral sedative and vaso dilator, but the writer seldom uses it except in cases of elderly or alcoholic patients.

145 Sanoecrysin in Tuberculous Meningitis.

J. V. LAMBE and P. A. BULLA (*Arch. med. et chir. y. esp.*, June 30th, 1928, p. 815), who record an illustrative case, maintain that the intraspinal injection of sanoecrysin should not be used in the treatment of tuberculous meningitis, since it produces an intense meningeal reaction and precipitates a fatal issue. Their patient was a man, aged 25, who was admitted to hospital with symptoms of meningitis. Lumbar puncture was performed and a solution of 8 mg. of sanoecrysin in distilled water was injected. Twelve hours later there was considerable aggravation of the symptoms, shown by acute delirium and considerable increase in the meningeal rigidity. The following day paralysis of the sphincters occurred, and death followed in coma. The cerebrospinal fluid withdrawn before treatment was under hypertension and clear, it showed a lymphocytosis and contained 0.25 per cent of albumin. At a second puncture a few hours before death the fluid was turbid and escaped with difficulty. The cell content was greatly increased and the albumin was 0.45 per cent, there was also a considerable quantity of bilirubin and some urobilin.

146 Postural Treatment of Arterio-sclerotic Gangrene.

ADVOCATING a more conservative method of treating gangrene than by amputation, L. A. REGNIER (*Minnesota Med.*, July, 1928, p. 455) adopts Buerger's classification of gangrene, and defines this condition as the death of tissues due to impaired or absent blood supply, and asserts that it can only be prevented by establishing an adequate collateral circulation. The conditions influencing its development, and the symptoms signaling its onset, are enumerated. Pathologically, diabetic gangrene does not differ from the arterio-sclerotic type, many clinical symptoms of impaired circulation may be absent in the former, but the arterial changes are the same, the large arteries alone being affected. To develop collateral circulation in the small arteries Regnier employs both postural and thermal (moist and dry) measures. Patients should be treated prophylactically, if possible, by the avoidance of long walking or standing, and exposure to cold and trauma. Postural treatment aims at producing ischaemia by elevation of the limb, this is followed by lowering of the limb to set up hyperaemia, and alternated with the horizontal position. This treatment, being drastic, is contraindicated in cases of extensive gangrene or where cellulitis or thrombophlebitis is present. Thermal treatment consists in keeping the limb as warm as comfort will allow by dry heat during elevation. This produces capillary hyperaemia, and is maintained for fifteen to forty-five minutes. The patient then sits up and the leg hangs down in a water bath at 50° to 105°, or, if ulcers, abrasions or moist gangrene are present, in saline solution or 2 to 4 per cent boric solution at the same temperature. This increases the hyperaemia of posture, maintains heat, and combats infection. After fifteen to thirty minutes with the limb in the dependent position the patient rests with the leg horizontally placed for an hour. Each treatment occupies two to three hours, and three or four are given daily. If patients cannot endure such long periods of treatment, these are shortened and the rest period lengthened. All foci of infection and systemic diseases, such as syphilis and diabetes, are actively treated. Five case reports showing the results from this therapeutic method are appended. Regnier maintains that amputation is a last resort, and can be prevented in many cases by a diligent local treatment such as has been described.

Neurology and Psychology.

147 Subacute Combined Sclerosis

M. J. BUBERT (*Journal Amer Med Assoc*, March 24th, 1928, p. 903) remarks that Russell, Batten, and Collier have attempted to prove that subacute combined sclerosis is not the result of, and not closely linked with, the anomaly of pernicious anaemia. Though this total dissociation is not accepted, their work shows that the neurological condition does not necessarily follow but may precede the usual pernicious anaemia picture and that the two conditions are probably results of the same, or closely allied, etiological factors, which are at present unknown. The pathology of subacute combined sclerosis consists of a focal destructive and a systemic lesion. In the former the changes lead to fibrosis with scarring and loss of all structure in the medullated sheaths and axis cylinders, the systemic degenerative process affects the long tracts of the cord, and eventually also leads to fibrosis and scarring. In view of the general pessimism as to the prognosis in pernicious anaemia complicated with spinal cord changes, Bubert reports an example which shows that in certain cases that have not progressed too far improvement follows dieting with liver. This case early associated with neurological symptoms, has been observed for nearly five years during the first part of which period, under the treatment then in vogue, the progress was steadily downwards. Early in 1926 the neurological condition was rather far advanced, as was evidenced by numbness and tingling in all the extremities, inability to appreciate the number and character of objects, extreme loss of equilibrium with resultant wobbly gait, which necessitated the use of two canes to permit of even halting walking, and complete loss of the patellar reflexes. The patient was depressed and irritable, he complained of failing memory and of his eyesight becoming dim. After one year of the Murphy diet the patient became bright and alert, and was able to walk briskly. His equilibrium became much better, as was shown by a negative Romberg sign and his ability to climb library ladders for books. The patellar reflexes returned, although they were hyperactive, the sensory disturbances entirely disappeared in the hands and arms and while still present in the lower limbs, were definitely improved. The condition of the blood was also markedly benefited.

149 The Nature of Ankle-clonus.

R. S. LYMAN (*Brain*, June, 1928, p. 168) declares that although usually associated with a pyramidal lesion, ankle clonus may occasionally have a physiological or functional etiology, and discusses the distinction between the organic and functional varieties. The varying opinions of many authorities as to whether ankle clonus occurs only in cases where an organic change in the cord exists or whether it is due to any one of several possible causes are cited. The flexion reflex implies as a rule, a definite organic lesion of the cord, but it is known to occur, in a somewhat altered form, physiologically in normal persons, according to Babinski, a clear distinction can be drawn between the physiological and pathological type of response. In the former there is a greater rapidity of withdrawal, shorter duration, prompter return to the original position, a more uniform amplitude of movement, and most important, flexion only at the hip and knee, but not of the foot at the ankle. Lyman reviews the conclusions held by many workers as to the antagonism existing between ankle clonus and the flexion reflex. He states that tendon jerks are subject to considerable variability, being affected by many causes such as exercise, drugs, and emotional factors, and, as one of the successive stages of reflex activity, ankle clonus appears when there is a sufficient increase of tone of the extensor muscles of the foot. He also asserts that the physiological limits of reflex activity are known to merge indefinitely into the pathological. The plantar response described by Babinski as pathognomonic of pyramidal lesion, has been found in certain toxic states in which no such obstruction has been demonstrated, true foot clonus may occur in certain conditions, such as anaesthesia, infection, and other toxic states as uraemia. Lyman has studied this question with Gordon Holmes in a number of patients, and describes a rapid and simple clinical test to distinguish organic from functional clonus. This consists of forcible plantar flexion of the homolateral hallux while ankle clonus is being maintained. If the clonus is then checked, the presence of an organic lesion in the central nervous system is inferred, if it persists despite prolonged toe flexion, it is probably functional in origin. The cessation of ankle clonus by flexion of the great toe in organic disease depends on an antagonism of reflexes. Clonus requires increased tone of the pedal extensor muscles. Forcible plantar flexion of the hallux gives rise to the withdrawal or flexion reflex in which there is strong tonic contraction of the pedal dorsal flexors which

causes reciprocal relaxation of the opposing extensors with disappearance of the clonus. Flexion of the great toe provides largely proprioceptive stimuli which make up the sensory portion of the arc relating to the flexion reflex.

150

Treatment of Phobias

M. J. JARKOWSKI (*Presse Méd*, March 14th, 1928, p. 323) indicates the psychotherapeutic measures which will be especially effective in the practical treatment of patients with phobias in early phases. He limits his subject to patients who, otherwise healthy, are afflicted with tormenting ideas, recognized as absurd, but accompanied by unbearable anxiety. In the study of these cases three questions arise: (1) Why does the idea torment? (2) Why does this idea differ from others in being so precise? and (3) What are the connections between the obsession and the idea to which it is linked? The first question is answered by the primordial law of human thought that the more an idea is combated the more is obsession caused. Jarkowski believes that the answer to the second is that it is pure accident, but adds that to obtain a clear idea it is necessary to trace the origin of the phobia. Lastly, he thinks that the interaction of the two phenomena—tormenting idea and anxiety—is complex and can be different in the various periods of the illness. In treating a patient with a phobia attention should not be given so much to the patient's anxieties and obsessions as to his conduct, which should be, at least in appearance, the principal object of the psychotherapeutic measure. The obsessions should be treated as a secondary matter. The patient's troubles must not be allowed to excuse his conduct or to disturb the life of his household. He must allow others to live, and live himself, a normal life in spite of his phobias, he must be made to understand that his troubles are not grave, but that they are largely due to a sequence of misunderstandings and mistakes. A clear idea must be given of the primary error which consists of the connection of his anxiety with an imaginary cause. He must be reassured in what concerns his secondary fears by showing him from his own experience that his anxiety never reaches that unimagined event which he dreads, and that phobia does not lead on to lunacy, but, on the contrary, is a protective mechanism. The simple explanation of these errors tends greatly to comfort the patient, but, still half convinced, he may object that whether it be a danger, an idiosyncrasy, or a simple mistake, it is none the less true that the tormenting idea pursues him and is unbearable. Jarkowski then appeals to the patient's goodwill, and demands from him an effort, stimulating his self-esteem, sense of duty, and ambitions, the nature of his miserable life being depleted if he refuses. But, above all, the patient's "egocentrism" must be combated, and his interest rekindled for the problems of life outside himself, and he must be made to feel the smallness of himself and of his preoccupations. Panic, like phobia, is shown by universal experience to be mastered only by curbing its impelling manifestations.

Obstetrics and Gynaecology.

150 Deliberate Early Rupture of the Membranes

I. KREIS (*Gynéc. et Obstét*, May, 1928, p. 421) doubts the physiological utility ascribed to the hydrostatic pressure exercised by the unruptured bag of membranes during the first and second stages of labour. That pressure, he states, is not only non-essential for expulsion of the foetus, but constitutes in numerous cases of non-engagement of the head the only obstacle to descent of the foetal pole into the pelvis whether normal or slightly contracted. Kreis relates in detail the course of (1) seven labours in which, with complete cervical dilatation, the head remained mobile until the membranes were artificially ruptured, (2) three cases in which rupture was quickly followed by delivery through a relatively contracted pelvis, (3) fifteen cases in which artificial or spontaneous rupture of the membranes, with only partial dilatation of the os, was followed by spontaneous expulsion in spite of foeto-pelvic disproportion. It is concluded that in the last group of cases the pressure of the amniotic bag impeded labour, causing spasmodic uterine contractions or preventing engagement of the head. According to Kreis artificial rupture may be indicated (whatever the degree to which dilatation of the cervix has advanced) when the uterine contractions are regular and strong, and labour nevertheless does not advance, or when deficient or spasmodic contractions have failed to become modified by medical treatment. This statement applies to the case of the relatively contracted as well as to that of the normal pelvis, but in the former instance the patient must be in hospital and there must be a reasonably good prospect of pelvic delivery. After rupture of the membranes a final "test of labour," with shaping of the foetal head thus ensues. The rupture is effected during the

height of a uterine contraction, slow drainage of the amniotic fluid being obtained by making a small opening as high and as far forwards as possible. Kreis is satisfied, from his own and other observations, that early rupture of the membranes is not associated either with a greater incidence of puerperal infection or a greater mean duration of labour.

151. Multiple Tumours of the Female Genitalia.

E. ALFIERI (*Ann di Ostet e Ginecol*, April 30th, 1923, p 381) describes a case in which a woman, aged 50, developed multiple tumours of the genital organs—namely, coincident basocellular carcinoma of the portio vaginalis of the cervix, spinocellular carcinoma of the ovaries, and adenomyoma of the uterus. The malignant tumours showed an abundant eosinophilia. The author believes that in most cases of multiple tumours the multiplicity is a pure coincidence, but in this case it would appear that organs embryologically and functionally related developed, simultaneously or successively, a proliferative reaction to some unknown stimulus.

152. Irritability of the Bladder

BELIEVING that bladder irritation in women has not received due attention, P. F. DONOHUE (*Minnesota Med*, July, 1923, p 478) asserts that the condition should always be considered merely as a symptom possibly indicating a serious pathological lesion. He shortly discusses the manifestations and gives an etiological classification of such cases, dividing them into two main groups—those with and those without bladder lesions. The former are subdivided into primary lesions and lesions secondary to extravascular disease, the latter being either temporary or permanent. Among the primary lesions acute cystitis, due to various causes, is occasionally seen. The condition is temporary, and rapid recovery is the rule. Subchronic cystitis (called also elusive ulcer or Heuner ulcer) and the Fewick ulcer are primary vesical lesions causing severe irritation. Foreign bodies accidentally introduced into the bladder give rise to irritability, which subsides on their removal. In cases of bladder neoplasms the cystitis is usually severe and resistant to any treatment short of destruction of the growth. Bladder diverticula may cause irritation due to persistent infection resulting from the residual urine. Disease elsewhere in the urinary tract or adjacent pelvic structures is primarily the cause of a vesical irritability in a large number of cases. Upper tract diseases causing this condition are pyelonephritis, pyonephrosis, lithiasis, and tuberculosis, gonorrhoeal or other infections of the urethra often extend upwards and involve the bladder. If the extravascular infecting focus is neglected the bladder lesions become more or less permanent, and such conditions as chronic cystitis, leucoplakia, and polyp, more resistant to treatment, may supervene. Irritation may occur in the absence of any pathological change in the urinary tract, and may be due to a disturbance in the myoneural mechanism controlling bladder function. It is seen in such diseases as *tuberc dorsalis* (most commonly), multiple sclerosis, transverse myelitis, and pernicious anaemia. Ureteral stone, and stricture or other obstruction, are also causes of this irritability, as are certain foods and drugs. Very rarely irritable bladder is merely a habit frequency, which has been noted in very nervous women. Donohue advises that in all cases a most careful investigation should be made to determine the site, extent, and nature of the responsible lesion; he believes that, if this were performed as a routine, the cases requiring major surgery or endangering life would be markedly decreased.

Pathology.

153. The Pathogenesis of Epidemic Encephalitis

DECLARING that an epidemic disease must be infectious and inoculable, J. SÉVAL (*Journ des Pratic*, June 30th, 1923, p 420) maintains that so-called epidemic encephalitis possesses neither of these properties, and controverts the usual theories as to its pathogenesis. He supports the hypothesis first advanced by Veillard, that it is an alimentary intoxication caused by poisons in the leguminous products substituted for ordinary flour. He thinks that it is not a new disease, and that its toxic symptoms cannot be attributed to the action of a presumptive virus. The various forms of encephalitis are classified according to their symptoms as high, low, peripheral, and mental, with their organic and psychio sequelae, a parallel is drawn between these and various intoxications, such as labyrinthism, beri beri, and pellagra, with their sequelae. It is pointed out that encephalitis first appeared during the war, in 1917, and was commoner among the belligerents, in whom the privations were greater than among the neutrals; moreover, influenza, another pandemic attacked chiefly the bread eating races. SÉVAL also doubts if the hypothetical dormitive virus is the causal agent of the fever occurring in the majority of cases of

encephalitis. He takes the case of pneumonia with delirium tremens supervening in an alcoholic, and remarks that no one would cite the delirium as the cause of the fever or as a specific pathological manifestation of the pneumococcus. In reality, the alcoholic toxins, normally controlled by the lacunar or circulatory antitoxins, have been freed by the intervention of an intercurrent infection. He terms the pneumonia a febrile "fire brand" malady, which permits the appearance of toxic symptoms, and he describes this as being a pyretic or post-traumatic liberation of the stored up toxins. A similar process is held to occur in encephalitis, in a patient progressively impregnated with toxins from vitiated bread, and attacked by some febrile infection such as influenza or angina, an encephalitis will be grafted on this infection as delirium tremens is grafted on pneumonia. The "fire brand" disease is epidemic, not the encephalitis itself. SÉVAL believes that this theory of encephalitis intoxication reveals the possibility of efficacious prophylaxis.

154. Bacterial Allergy in Recurrent Erysipelas

K. E. BIRKHAUG (*Journ Amer Med Assoc*, June 23rd, 1923, p 1997) during the last three years has actively immunized sixty-eight patients by means of gradually increasing doses of *Streptococcus erysipelas* toxin alone or a mixture of the toxin and the killed streptococci. Although many of these patients suffered the usual discomfort attending a course of immunization with bacterial antigens, only six showed erysipelas like eruptions along the routes previously affected by the recurrent attacks of erysipelas. In three cases which were studied bacteriologically and immunologically (the outstanding features were—(1) the recurrence of erysipelas in the identical situations previously affected or sensitized; (2) the absence of *Streptococcus erysipelas* from the lymph spaces within the erysipelatous lesion, where the organism was present in almost every case during the acute stage; (3) the isolation of *Streptococcus erysipelas* from distant foci of infection, such as the tonsillar crypts or nasal recesses, and the demonstration in the blood of erysipelas toxin presumably absorbed from these foci, and (4) the development of antitoxic substances following the injection of the erysipelas toxin vaccine, which subsequently immunized against recurrent attacks. Birkhaug suggests that the existence of a state of bacterial allergy accounts for the recurrent attacks of erysipelas strictly within previous sensitized anatomical areas.

155. Respiratory Sequels of Gall bladder Distension

V. L. SCHRAGER, A. C. IVY, M. KRONENBERG, and P. DEXSANT (*Surg., Gynecol. and Obstet*, July, 1923, p 1) investigated clinically and experimentally the symptoms produced by distension of the gall bladder and biliary ducts, having observed that some cases of biliary colic from distended gall bladder or impacted stone are associated with respiratory embarrassment at the height of an attack. The gall bladder in dogs was distended by the introduction of a small water-filled balloon to which a manometer was attached. Readings of the respiration and blood pressure were then recorded. In experiments to ascertain the effects of distension upon the cystic and biliary ducts a cannula was tied into the cystic duct through the gall bladder, the common bile duct was doubly tied, and all branches of the vagi and splanchnic nerves and sympathetic were cut. The reflex manifestations noted during distension were distress, inhibition of the respiration, inspiratory in type, occasionally salivatory denoting nausea, and vomiting. The distress from distension of the gall bladder was not so marked as was that accompanying distension of the biliary passages, and the amount of pressure necessary to cause inhibition of respiration was less than that required to cause salivation and distress. It was found that nausea, vomiting, and some of the respiratory inhibition were abolished by section of the vagi, cutting the right splanchnic nerve abolished distress and some respiratory inhibition. The subcutaneous injection of cocaine or the instillation of cocaine or procaine into the bile ducts was found to ameliorate or temporarily abolish the effects produced by distension, blocking of the right splanchnic nerve with procaine or alcohol under direct vision produced results similar to those produced by section. Changes occurred in the blood pressure and heart rate during distension, but these were not uniform, and appeared to be dependent upon the functional condition of the cardiovascular system at the time the distension occurred. Distension of the biliary ducts was produced by intermittent distension over a period of a week, and during the respiratory inhibition produced by distension the diaphragm was observed to be contracted on the right side, apparently for the purpose of demobilizing or splinting the affected part. It is concluded that in differential diagnosis this symptom of respiratory inhibition or embarrassment in affections of the gall bladder and biliary ducts is of value, since it is practically absent from any other abdominal complex.

Medicine.

154.

Transient Hemiplegia.

O. K. WILLIAMSON (*Journ Med Assoc of S Africa*, May 26th, 1928, p. 269) describes three cases of transient hemiplegia in elderly patients, he ascribes this to arterial spasm which did not persist long enough to produce softening in the cerebral area involved. After a fall a man, aged 62, became comatose and deeply cyanosed. The respiration was stertorous, of the Chayne-Stokes type, the pupils were tightly contracted, the pulse was small and weak, the tongue was deviated to the right, knee jerks were absent, and there was flaccid paralysis of the right arm and leg. When soon he was still cyanosed, but conscious and fairly rational. The pupils later became equal and rather large. The deviation of tongue, the facial paralysis, and the weakness of the right arm soon passed off, but the paralysis of the right leg persisted. The knee jerks returned and there was no ankle clonus. The plantar reflex was extensor on the right side and flexor on the left. The heart sounds were normal, the radial pulse was rather small, regular, and soft, and the arteries were not perceptibly thickened. *Aspirin* was given immediately, orythol tetranitrate in $\frac{1}{2}$ grain doses was ordered every four hours, and 8 grain doses of potassium iodide thrice daily. A few days later all signs of paralysis had disappeared. Before the attack his systolic blood pressure had been 140 mm Hg, and the diastolic pressure 90 mm. Williamson believes that spasmodic contraction of the middle coat of the middle cerebral artery produced temporary ischaemia. His second patient, a man aged 55, had had attacks of paresis in the left arm and leg for two months associated with vertigo and headache, with complete paralysis of arm, and paresis of the leg with numbness in both limbs, they were followed by unconsciousness lasting about thirty minutes, when he occasionally passed urine. He had had six similar attacks. There was no paralysis and the knee jerks were normal. The brachial arteries were thickened and tortuous. The systolic blood pressure was 185 mm. His third patient, a woman aged 64, suffered from occasional sudden weakness of the left hand, with numbness and tingling in the left thumb and index finger. The mouth was drawn to the left, and there was numbness and coldness of its left side. These symptoms persisted for about a week. The patient was florid and well nourished, there was no paresis, and the knee jerks were normal. There was no obvious thickening of the arteries, and the systolic blood pressure was 210 mm Hg. The heart was dilated, there were no bruits, but the aortic second sound was accentuated. At the time of an attack the pulse was small and weak, but later recovered its volume. Williamson remarks that it has been noted previously that sclerosed vessels are especially prone to conditions of spasm and adds that it is obviously most important to recognize and treat these cases as early as possible. Eliminatory measures and vaso-dilator treatment are indicated.

157

Adult Apical Pneumonia.

R. LEPAGE (*Bruxelles Médical*, August 12th, 1928, p. 1337) remarks that adults are not immune to apical pneumonia, a disease common among infants, pneumonia accounts for 25 per cent of the mortality of old age, and two-thirds of these pneumopathies occur in the upper lobe. He adds that young adults, though less frequently than the aged, are also attacked. Its diagnosis is not always easy owing to its relative rarity, its unusual localization, and its symptomatology. The onset is generally sudden, with chills, pain at the base of the thorax, and elevated temperature, it seems what resembles that of frank lobar pneumonia, but is less severe and dramatic, the typical sputum and distinct localizing signs being absent. Symptoms of general infection, among which nervous reactions (vomiting, restlessness, delirium, prostration, and torpor) predominate, are very persistent, but respiratory signs are very slight, a sharp dyspnoea, ordinary cough with no or scanty sputum, and some bronchial rales only being present. A sign of great diagnostic value is a heavy furring of the tongue. Those symptoms last for four or five days or even longer, and then the signs of apical involvement appear. At times a sub-clavicular skodism, a souffle or some isolated rales are present, sometimes there is dullness over the suprascapular fossa with adventitious bruits, and sometimes rales are heard over the apex of the axilla. The dullness and sputum are not early signs, the latter is not typical and does not appear till defervescence, which is as sudden as the onset. Six cases

illustrating these points are reported, the ages of the patients ranging from 19 to 32. Death occurred in only one of those. The thoracic pain, an early symptom, occurs on the same side as the lesion and always at the base of the thorax. When this pain is very severe and on the right side, and especially if icterus is also present, an erroneous diagnosis of hepatic colic might be made. More or less marked congestion of the bases and even effusion, were found in five of the cases. Conditions usually considered as predisposing to this type of pneumonia are debilitating and cachectic diseases, such as alcoholism, diabetes, and cancer, but Lepage adds that none of his cases showed these classic predispositions, and that the only death occurred in a robust female patient, aged 19, in whom, without any apparent cause, a double bronchopneumonia developed. The treatment of apical pneumonia is purely symptomatic, though vaccine therapy may be tried.

158 Pirquet and Wassermann Reactions in Asthma.

K. J. BAAGØE (*Brit Journ Child Dis*, April-June, 1928, p. 107) states that the relation between tuberculosis and asthma is one on which widely divergent views have been held. The question has become of renewed interest owing to the studies of Storm van Leeuwen and Varkamp, who maintain that patients with allergic diseases possess a special hypersensitivity to tuberculin. This was shown (1) by most of their patients with asthma and hay fever giving an undoubtedly positive Pirquet reaction, (2) by the excellent result claimed from treating such patients with tuberculin, and (3) by the occasional occurrence of asthmatic attacks as the direct result of an injection of tuberculin. Baagøe, however, found from investigations on 83 asthmatic children aged from 2 to 15 years that a positive Pirquet reaction was not more frequent than among ordinary hospital children, thus confirming Wallgren's view that there is no etiological connexion between hypersensitivity to tuberculin and asthma. Examination of the Wassermann reaction in 92 asthmatic children aged from 3 to 15 showed that it was invariably negative, except in a syphilitic child, so that syphilis does not appear to play any part in the development of asthma, as some writers maintain.

Surgery.

159

Angioma of Kidney

E. S. JUDD and H. SIMON (*Surg Gynecol and Obstet*, May, 1928, p. 711), who report a personal case, illustrate the rarity of angioma of the kidney by the fact that they could find only eleven other examples on record. The principal clinical manifestations consist in haematuria, which is usually the result of ulceration into the renal pelvis. The bleeding may be severe enough to cause marked anaemia or a state of shock. No symptoms, however, may occur when the angioma is in the renal cortex. In the reported cases the only definite symptom before operation was bleeding from one kidney without any obvious cause. The diagnosis of essential haematuria has often been made until the continuation of haematuria necessitated nephrectomy and the angioma was found. Renal angiomas probably never attain a greater diameter than one or two centimetres. They are usually solitary, but Henry Morris recorded an instance of multiple tumours situated in the medulla, while in Deansley's and Virchow's cases multiple tumours were found in the cortex. These tumours may or may not be encapsulated. The age of the patients in the recorded cases ranged from 18 to 66, the average being 38 years. Of the seven cases in which the sex was mentioned five were in males, and in five out of seven cases the tumour was on the left. The authors remark that a true angioma must be distinguished from other blood containing tumours which may occur in the kidney, such as carcinoma, which is differentiated by the type of epithelium lining the blood filled spaces, or haemorrhagic cysts, which are usually much larger than angiomas. The authors' patient was a woman, aged 57, who for twenty years had had attacks of haematuria occurring every four or five years and lasting two or three weeks. Cystoscopy showed that there was less excretion from the left kidney than the right. In view of the history of repeated renal haemorrhage associated with pain which was always referred to the left side, an exploratory operation was made, when the upper pole of the left kidney was found to be occupied by many dilated blood vessels, nephrectomy was performed and recovery was uneventful. Examination of the tumour, which was situated in the cortex and measured 1.5 by 2.5 cm, showed the typical appearance of angioma.

160 Fracture Involving the Acetabular Cavity

C LENORMANT (*Presse Méd*, June 23rd, 1928, p 788) reports a coincidence whereby two men suffered a simultaneous fracture of the acetabular cavity. The patients, who were each about 40 years old, were seated side by side in a motor car when a violent collision with another vehicle occurred. The impact threw them both on the ground, though neither knew precisely how this happened. The one complained of pain in the hip and was unable to walk, the injured hips were the adjacent ones as they sat in the car, the right one being that of the driver, and the left one of his passenger. Examination on the following day did not definitely disclose the nature of the lesion. The driver's leg maintained a fixed attitude of incomplete extension with adduction and internal rotation. The radiograph revealed a fracture of the acetabulum. In the other case the leg was immobilized in a position of semiflexion without adduction or abduction, but with slight internal rotation. This patient suffered acute pain during the examination. An x-ray examination showed a fracture of the superior acetabular ridge with the fragment detached. The author discusses fractures in this region and defines two anatomical types—one in which fracture is limited to the acetabulum, and the other in which the ischium, pubis or ilium is involved also. In the more severe form the head of the femur is driven into the pelvis. He emphasizes the importance of careful radiological examinations in all suspected cases, both for the first diagnosis and also during the course of treatment.

161. Epinephrectomy in Spontaneous Gangrene.

V A OPPEL (*Annals of Surgery*, June, 1928, p 801) follows up his contention in 1911 that the condition of spontaneous gangrene was due to a hyperfunction of the adrenal bodies and was caused by a hyperadrenalinæmia, by presenting clinical and experimental proof that his hypothesis was correct. He suggested that an excess of adrenaline in the blood caused spasm of the arteries, a derangement of the degree of nourishment to the arterial walls, orosion of the endothelium, development of arteriosclerosis, formation of sclerosis, and production of a local thrombus which impinged, as it grew, on the lumen of the artery. He contends that Snegor's disease and hyperadrenal arteriosclerosis are both the same condition, which he calls spontaneous gangrene. For the cure of this disease he has performed a left-sided epinephrectomy in 130 cases with small mortality—only two deaths occurring in the last 70 cases treated in this way. After the operation the number of thrombocytes and the level of blood sugar decrease, the central arterial pressure becomes lower, and the peripheral blood pressure rises. It was also observed that pulses reappear in the arteries, which cease to be in a state of spasm, and that after operation the gangrene is arrested, pain stops, dead tissues slough away, and movement is regained in the affected extremity. Epinephrectomy has also proved satisfactory for the relief of Raynaud's disease, after which there is improvement of the function of the heart. As a result of his observations Oppel considers that the condition of spontaneous gangrene is caused by hyperadrenalinæmia irritating the sympathetic nervous system, with resultant spasm of the arteries.

162. Surgical Treatment of Azoospermia

M RICHARD (*Deut Zeit f Chir*, July, 1928, p 275) reviews the present position of conservative surgery of the testis. He refers to the earliest resections of the epididymis performed more than seventy years ago, and to the modifications introduced by later surgeons. The results of these operations were recorded but seldom, although a few were successful. Richard describes a number of experiments on guinea pigs, rabbits, and dogs, he also compares the results of operations on patients recorded by various modern surgeons. His conclusions are as follows: (1) The probability of anatomical and functional connexion between the testis and the vas deferens after oxtidation of the entire epididymis is very slight. Hitherto no biological evidence of such an anastomosis has been adduced. For this reason, and because of the danger of recurrence of the disease, resection of the epididymis in tuberculous epididymitis must be considered absolutely. (2) There is much greater probability of a successful anastomosis between the healthy remains of the epididymis and the vas deferens. This operation is advisable to relieve the azoospermia of post-gonorrhoeal obliteration of the lumen of the vas, and in chronic non-specific epididymitis. (3) There is considerable probability of the restoration of the lumen of the divided vas deferens, after splitting the divided end of the vas and lateral anastomosis with the distal portion of the canal. It would appear that atrophy of the testis and arrest of spermatogenesis occurs only when the spermatic artery is divided or injured.

Therapeutics.

163. Cerebral Opothrapy in Epileptic Subjects with Malaria

A LOMBARDI (*Rev Sud Amer de Endocrinol, Immunol, Quimioter*, June 15th, 1928, p 389), who records five illustrative cases, states that quinine is contraindicated in epilepsy owing to its tendency to produce convulsions. Epileptic subjects, therefore, who contract malaria, as often happens in Calabria, are liable to be deprived of the benefits of a specific remedy. Lombardi, however, has found that the administration of cerebral extract by mouth or subcutaneously not only improves the general condition of the epileptic patient by diminishing the number and severity of the attacks, but also presents the following advantages: (1) It neutralizes the exciting action of quinine on the motor centres of the cerebral cortex and allows the patient to undergo specific antimalarial treatment. (2) It renders the administration of quinine possible in any other cases in which it is required, such as acute infectious diseases. (3) Subcutaneous injection of cerebral extract enables the epilepsy to be treated when the patient is suffering from gastro-intestinal disturbances which do not permit any drugs to be taken by mouth.

164 The Antigen Treatment of External Tuberculosis.

A HENRY (*Arch del Inst Pasteur de Tunis*, June, 1928 p 157) has treated more than fifty cases of various forms of external tuberculosis with the methyl antigen of Nègre and Boquet, and gives a summary of excellent results obtained in twelve cases, two of lupus being dealt with in greater detail. This antigen is said to be easier to prepare and more stable than the peptonized antigen B2 of Calmette and Massol, and to cause an abundant formation of antibodies. Six weeks old bouillon glycerol cultures of human and bovine bacilli are used in its preparation. The bacilli are defatted with acetone and then treated with methyl alcohol. The extract thus obtained is cleared of the alcohol by distillation in a vacuum, and is then emulsified in equal quantities of physiological saline. The antigen is used both undiluted and in a 1 in 10 dilution, and treatment is always commenced with the diluted form, the subcutaneous method being employed. The commencing dose is 1/4 c cm, which is progressively increased to 1/2, 3/4, and 1 c cm, the same progression being followed with the undiluted antigen. The same dose is injected three or four times successively before the next higher is commenced. Injections are given twice a week and the 1 c cm dose is continued for a long period. If pyrexial or local reactions occur, return to a lower dose is advised. According to Henry, methyl antigen causes no ill effects if a progressive dosage is maintained, its use is said to be efficacious in the treatment of open or closed adenitis, osseous fistulae, cutaneous tuberculosis, and lupus. It has a rapid, beneficial action on the general state, the weight increasing and the skin improving.

165 An Aromatic Bismuth Preparation.

R N CHOPRA, J C GUPTA, and M N MULLICK (*Indian Med Gaz*, July, 1928, p 361) remark that the older preparations of bismuth were not suitable for injection but only for oral administration, and that during the past decade several new compounds have been prepared with the view to employing them intravenously or intramuscularly. Most of these have proved unsatisfactory for intravenous injections, and even when given intramuscularly have caused much pain and discomfort. The insoluble compounds, though not so painful as the soluble, are not absorbed quickly and regularly, and so give rise to the danger of cumulative poisoning. When administered intravenously bismuth compounds produce agglutination and haemolysis of the erythrocytes, and even such compounds as the colloidal preparations, which do not bring about these results, cause severe reactions, cases of sudden death with symptoms of colloidal shock following the intravenous injections of such compounds have been reported. B C Ghose has prepared an organic aromatic compound, which is practically the bismuth analog of urea stibamine, and has been given the name of "bismene." It is a sodium salt of para amino-phenyl bismic acid in combination with urea, and contains 50.1 per cent of bismuth. This salt is freely soluble in water (15 per cent at 33° C), giving a clear, brown, slightly acid solution (pH = 5.9) which is not decomposed by boiling. It has a low toxicity, and is said to cause no untoward effects after intravenous injection. The authors have used this preparation with striking results in cases of framboesia, and are now trying it in syphilis and filariasis. Four cases of framboesia are reported in which the lesions rapidly cleared and the general health considerably improved after four intravenous injections given weekly in progressive doses of 0.05, 0.1, 0.15, and 0.175 gram.

Dermatology.

166. Psoriasis and Affections of the Joints

E. ZELLNER (*Wien Arch f Inn Med*, July 20th, 1928, p. 435) refers to several articles published during the last twenty years by French and German writers on a specific arthropathy associated with psoriasis, which must not be confused with the syphilitic or gonorrhoeal forms. He has seen eleven cases of psoriasis accompanied by definite articular disease, all these patients had negative Wassermann reactions, and only two men, aged 68 and 59 respectively, had had uncomplicated gonorrhoea during adolescence. Zellner classifies eight of these patients as suffering from psoriatic arthropathy. The ninth patient was a woman, aged 47, who had suffered from psoriasis since the age of 10. She was neurasthenic and complained of swelling and pain in the joints, but no articular lesions were found. The tenth patient was a man, aged 23, who had psoriasis, accompanied by signs of arthritis deformans. The eleventh patient, a woman aged 25, had typical psoriasis accompanied by a form of tuberculous polyarthritis (Poncet) with tuberculous pulmonary lesions. The arthritis was mild and yielded to specific treatment. Zellner describes the last three cases in order to show the contrast between psoriatic arthropathy and other forms of arthritis occurring in patients suffering from psoriasis. In the cases of psoriatic arthropathy, the joints affected were chiefly the wrists, fingers, and toes. In some cases the knees and shoulders were attacked subsequently. The affected joints were swollen and very painful on pressure or movement. The arthritis was progressive, and severe disorganization of the joints occurred. Zellner states that five of these patients were males and three were females; this is contrary to the sex ratio of chronic progressive polyarthritis. Psoriatic arthropathy occurs almost always symmetrically in the small joints, the larger joints are attacked later, but in one case the first articular pains occurred in the knee. Skiagrams often show similar changes in psoriatic arthropathy and chronic progressive polyarthritis, but the differential diagnosis is usually easy, arthritis deformans in the monoarticular or symmetrical forms most frequently affecting the knee joints. It is a disease of later life, more common in women, especially in the climacteric and post-climacteric periods. Ankylosis never occurs, and skiagrams will distinguish arthritis deformans from psoriatic arthritis. Arthritis deformans may attack a patient who suffers from chronic psoriasis, but this does not justify the assumption that the two diseases have a closer connexion. One patient had arthritis deformans of the knee joint in addition to psoriatic arthritis in other joints. The differential diagnosis from polyarticular diseases of infective origin, such as gonorrhoeal arthritis, is important. In gonorrhoea skin affections resembling psoriasis may occur, and these are always connected with joint lesions. Differential diagnosis is particularly difficult in chronic polyarticular forms of gonorrhoeal arthritis. In some cases urethritis may be demonstrated. Skiagrams may aid differential diagnosis of both gonorrhoeal and syphilitic polyarthritis. In the latter there is a positive Wassermann reaction in the early stages, but a negative reaction may not indicate that the lesion is non-syphilitic. Early cases of syphilitic arthritis recover under treatment without destruction of tissue. In suspected cases the therapeutic test should always be performed. Extreme ankylosis occurs seldom in late syphilitic arthritis, but are common in psoriatic arthropathy. Tuberculous arthritis may be differentiated by the tuberculin reaction, but it must be remembered that atypical psoriasis may be associated with tuberculous or gonitic arthritis.

167. Dermatomyositis of the Extremities

REMARKING that dermatomyositis, or so-called ringworm of the feet and hands, is occasionally extremely difficult to cure, C. WHITE (*Journ Amer Med Assoc*, June 9th, 1928, p. 1865) reports the clinical observations, laboratory reactions, and therapeutic details of three cases selected from a series of eighteen. All these patients suffered from a resistant dermatomyositis, and examination of the peripheral blood vessels revealed the presence of an obliterating occlusive endarteritis. In the three cases discussed previous x-ray treatment had only aggravated the condition, and the external application of the usual fungicides produced no effect. General examinations, and particularly those of the vascular system, suggested that circulatory impairment might be a factor favoring fungus activity, and that an increase of the peripheral circulation together with the local applications might overcome the infection. Accordingly, intravenous injections of a 20 per cent sodium citrate solution were given, local treatment being continued, and strikingly good results were obtained. The injections were given on alternate days, the initial dose of 5 c.cm. being gradually increased to

10 to 20 c.cm. Usually the drug is well tolerated if given slowly. The maximum dose administered was 20 c.cm., but many patients could not take more than 10 c.cm. because of the production of tachycardia, faintness, and a feeling of impending collapse. White adds that the dosage should always be kept below the point of any systemic reaction. Local therapeutic measures are very important, but too strong preparations should be carefully avoided. C. E. Brown has divided peripheral vascular disturbances into functional and organic, the chief distinction between the two being the palpability of the pulsation. As the pulse was markedly diminished or absent in all the cases, the circulatory impairment would fall in the organic group, while clinically there was impairment of the vascular supply in the larger vessels, the necroses must be attributed to partial or total thrombosis of the smaller arterial branches. There were no clinical features of thrombo-angiitis obliterans. W. A. Steel has used sodium citrate extensively in the treatment of the latter disease, and believes that it exerts a specific action as well as reducing the viscosity of the blood. Since, however, the drug produced no improvement in three patients with mycosis of the foot but with no detectable peripheral arterial sclerosis, the present author suggests that it exerts its beneficial effects by inducing a physiological improvement of the circulation, indirectly increasing the resistance of the local areas.

168.

Pigmentary Urticaria.

THOUGH pigmentary urticaria is usually considered as occurring in early life, often shortly after birth, L. M. PAUTRIER, A. DISS, and WALTER (*Bull Soc Française de Dermatol et de Syph*, April, 1928, p. 254) maintain that as a rule the onset is delayed. An example of this is recorded in a man, 64 years old, in whom the disease first appeared at the age of 50. The affection was of sudden onset and invaded the whole body, excepting the face and neck, at once. The eruption consisted of small, round, black papules, sometimes isolated, sometimes confluent, with regular borders of a colour ranging from red to brown. These papules were clearly pigmented, infiltrated, and raised above the skin. On gentle pressure, a pale red zone, surrounded by an erythematous halo, appeared round each papule, which persisted for half an hour. Repeated friction of the body caused a diffuse erythema, which surrounded the lesions, had a tendency to become confluent, and lasted for some hours. On microscopic examination, these papules or dermic tumours were seen to consist of a great number of cells, some round and globular and some polygonal, with numerous protoplasmic expansions. All the cells were studded with granulations varying in colour from red to blue and violet, and these basophilic and metachromatic granules characterized the cells as being mastocytes. Numerous capillaries, apparently newly formed, were also seen running vertically to the epidermis. The mastocytes extended as far as the epidermis, and, in general, the metachromatic granules stopped at this layer, while the cellular expansions carrying them had invaded the epidermal basal layer. At certain points, however, the granules were found in the epidermis. It was evident, therefore, that the mastocytes had deposited the granules they had elaborated in the epidermal cells, and, conversely, melanic granules, elaborated in the epidermis, were deposited in the mastocytes. The authors regard this as a typical case of pigmentary urticaria with mastocytic tumours, which presented dermo-epidermic exchanges between the dermic mastocytes and the pigmentogenous cells of the epidermis.

Obstetrics and Gynaecology.

169. Induction of Labour by Quinine and Pituitrin

R. DE GUCHTENEERE (*Bruxelles Medical*, July 15th, 1928, p. 1203) comments on the value of a combination of ecbolic drugs in inducing labour. It has been stated that in the quinine and castor oil method the former drug merely stimulates the rhythm of contractions induced by the castor oil, pituitrin, on the other hand, is inconstant in its action on the uterus, although it hastens the process of induction. A combination of these two drugs so as to obtain the ecbolic effects of both is stated by the author to have proved successful in 90 per cent of cases. The indications are primarily post maturity, which, according to various authors, occurs, in at least a minor degree, in from 10 to 19 per cent of pregnancies. The author's method is as follows: A total of 2 grams of quinine is given in four doses at half hourly intervals; the doses may be reduced if there are signs of intolerance. With the last dose 0.25 c.cm. of pituitrin is injected. This is repeated at half hourly intervals, four or more doses being given, and labour is induced in about six hours. It occurs more rapidly in primiparae. No ill effects

have been noted, with the exception of those due to quinine intolerance. There are certain contraindications to the use of pituitrin, such as cardiac or renal disease, arterio sclerosis, high blood pressure, and malpresentations.

170 Diagnosis of Commencing Cancer of the Cervix.

W. SCHILLER (*Arch f Gynäk*, February 25th, 1928, p 211) discusses the diagnosis of very early carcinoma of the cervix. He is satisfied that just as in the later stages a superficial extension may precede deep penetration of the neoplasm at right angles to the epithelial covering, so in the very earliest stages the neoplastic change, which invariably commences near the external os, proceeds centrifugally along the surface of the cervix. For microscopical diagnosis of commencing carcinoma, it is therefore better to scrape away the epithelium from the surface than to excise more deeply a macroscopically suspect area. Macroscopically the cancerous areas are usually found to be pale and to resemble patches of leukoplakia. In four out of 135 cases in which during six months the uterus was removed for other conditions, systematic histological examination revealed an unsuspected early carcinoma of the cervix. Schiller defines the pathological cytology as "anaplastic atypia and polymorphism" of the epithelial cells. In the very earliest stages the epithelium is as definitely marked off from the underlying connective tissue as in normal conditions, but both in the basal and superjacent layers neighboring epithelial cells and their nuclei are of differing size and shape, with variable staining properties. The nuclei are relatively more numerous than in the healthy epithelium, from which the early carcinomatous area is marked off by a sharp and unusually oblique line of demarcation. Irregularity of the papillae and disappearance of the prickles between the polygonal cells may occur, but not necessarily, in early cases. Neither absence of mitoses nor absence of penetrations of the epithelium deep into the connective tissue excludes the diagnosis of carcinoma. Inflammatory infiltration beneath the carcinomatous zone is usually noted. Schiller admits that diagnosis in these cases demands special experience on the part of the histologist; it is easier when, together with the carcinomatous area, a portion of normal tissue has been removed for examination. He discusses the fallacies which may be encountered when a healing erosion is examined histologically. W. Schiller (*Zentralbl f Gynäk*, July 28th, 1928, p 1886) has found that if a swab impregnated with Lugol's iodine solution be placed for a short time in contact with the surface of the cervix, normal epithelium becomes stained dark brown within a few seconds, whereas diseased epithelium, including epithelium which microscopically shows signs of early carcinomatous change, remains unstained or becomes faintly tinged with yellow. The differential staining, which is temporary but can be repeated with a similar result, occurs even more quickly after the application of very weak potassium iodide solution. The test is said to have no value in the diagnosis of early carcinoma from inflammatory or other morbid conditions, but to be of considerable use when a biopsy is to be performed in cases of suspected carcinoma of the cervix. If after the application of iodine the portion of tissue excised or scraped away for examination is selected from the faintly staining zone, there is no risk that normal instead of diseased tissue may be subjected to the microscope. Faint staining with iodine is also a characteristic of areas of more advanced carcinoma, so that after Wertheim's hysterectomy application of iodine to the vaginal mantle will show whether the excision has been carried wide of the furthest extension of the neoplasm.

171 Sex Differences in Syphilis.

A. S. WARTHIN (*Amer Journ of Obstet and Gynecol*, May, 1928, p 595) states that in a very large number of cases the primary sore in women escapes detection either by the patient or the doctor. It is as a rule smaller, less indurated, and more fugitive than in the male, while syphilitic infection without chancre probably occurs frequently on columnar celled mucosae. A striking exception to these common characteristics is the occurrence upon the cervix, clitoris, urinary meatus, and nipple of hyperplastic cauliflower-like chancres, usually mistaken clinically for carcinoma. In the secondary stage the cutaneous lesions are generally milder in women. They may even be so slight as not to be noticed, or they may not appear at all. On the other hand, a greater proportion of women have constitutional symptoms, especially fever, diffuse headache, and anaemia, together with relatively greater involvement of the heart, aorta, central nervous system, and ovary, as compared with the testis. Lesions of latent syphilis are usually more extensive in the female liver, pancreas, adrenals, and rectum, but severe clinical forms of these visceral lesions are infrequent in comparison with the severe forms of cardio-vascular and central nervous system syphilis in men.

Pathology.

172 Vaccination of Cattle with B.C.G.

B. LANGE and K. LADTIV (*Zeit f Hyg u Infektionskrankh*, July 3rd, 1928, p 803) have performed experiments on a small number of cattle to find out whether vaccination with the B.C.G. strain has any protective effect on subsequent infection with virulent tubercle bacilli. One protective dose only was given, either 160 mg subcutaneously or 20 mg intravenously. The infecting dose was given about four to six months later, it consisted of 2 mg in one experiment, and of 20 mg in another experiment, of a moderately virulent bovine bacillus (the Vallée strain) given intravenously. The results suggested that no protection was conferred by subcutaneous vaccination, but that a certain amount was afforded by intravenous vaccination. The protection, however, was noticeable only when a small dose (2 mg) of virulent bacilli was used for the infecting test; this dose was not certainly fatal to control animals. When a larger dose (20 mg) was used both the control animals and the subcutaneously vaccinated animals died of miliary tuberculosis, unfortunately no intravenously vaccinated animals were used for this test. The authors seem to think that the only chance of protecting cattle with the B.C.G. strain is by intravenous vaccination; they cast grave doubt on the efficacy of the oral method of administration which Calmette is at present using for children, but they intend to test the value of this method on newborn calves.

173 Punctate Basophilia in the Lead Treatment of Malignant Disease.

R. W. BROOKFIELD (*Journ Path and Bact*, April, 1928, p 277) has made a study of the blood changes during the course of treatment of malignant disease by lead, paying special attention to the production of punctate basophilia. The effect of the lead varied greatly in different patients; some patients underwent a whole series of injections without showing any great fall in the red cell count, while others lost half their red cells after a single dose, and later showed extreme bone marrow activity and marked basophilia. From a study of red cells vitally stained by cresyl blue the author is of the opinion that cells showing punctate basophilia are closely allied to reticulated cells—that they are, in fact, immature cells or reticulocytes altered by the toxic action of lead. The evidence on which he bases this opinion depends on the variation in appearance produced by staining with different concentrations of cresyl blue. Using concentrations of 0.2 to 5 per cent the cells show an unfragmented reticulum, with a 0.05 to 0.1 per cent dilution they show a fragmented reticulum with stippling and a certain amount of polychromasia, with concentrations below 0.05 per cent there is no reticulum, but the cells show stippling and polychromasia—that is, according to the strength of the stain, there is a complete transition from the typical reticular cell to the cell showing punctate basophilia or polychromasia.

174 Relation between Glanders and Melioidosis.

J. VERGE and O. PAIRFMAURE (*C R Soc de Biologie*, June 22nd, 1928, p 182) have found that the serum of a glandered horse is able to fix complement in the presence of an antigen made with *B. whitmorei*. The antigen was prepared by autoclaving a one week's broth culture for half an hour at 115° C, centrifuging, washing, preserving the deposit on ice, and suspending 40 mg in 20 c.c. of saline at the moment of usage. In the presence of this antigen the horse's serum fixed complement to the same extent as it did in the presence of an antigen made up with *B. mallei*. This observation confirms Stanton and Fletcher's observations on rabbits, and demonstrates the close antigenic affinity of *B. mallei* and *B. whitmorei*.

175 The Incubation Period of Yellow Fever in the Mosquito

J. H. BAUER and N. P. HUDSON (*Journ Exper Med*, July, 1928, p 147) recall the fact that previous observers have demonstrated the existence of an incubation period in the mosquito during which, after a meal of infected blood, it remains incapable of transmitting yellow fever to susceptible persons. The length of this incubation period has been found to be about twelve days. Working with *Macacus rhesus* monkeys the authors have confirmed this observation, in one experiment the mosquitoes became infective by the ninth day, and in two other experiments not till the twelfth day. But it was found that if at any time after feeding on an infected monkey the mosquitoes were ground up and injected into fresh monkeys these monkeys developed typical yellow fever. This means that the yellow fever virus can be demonstrated in an infectious form in *Aedes aegypti* throughout the entire period of extrinsic incubation, even though the mosquitoes do not become infective by biting till the ninth to the twelfth day after infection.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine.

176 Complications of Helminthiasis

L. SOUBEN (*Bull Soc de Théor*, April 18th, 1928, p 110), who records seven illustrative cases in children and adults, emphasizes the frequency of the medical and surgical complications of helminthiasis, the possibility of which should always be borne in mind in order to prevent serious errors in diagnosis. The condition should be suggested by such symptoms as gastric disturbance, with foetid stools, nasal, buccal, and anal pruritus, conjunctivitis, erythematous nausea, vomiting, peculiar fetor of the breath, and a characteristic paroxysmal cough. The ova may be looked for in the stools, but the simplest method is to employ a therapeutic test. Seabon has always obtained good results with calomel and santonin in very small doses. Lumbar puncture causes cessation of convulsions and a return of consciousness. In the child cerebrospinal fluid in such cases is abundant, perfectly clear, and cytologically and bacteriologically normal. In adults Souben twice found slight excess of albumin and once a turbid fluid, but no micro-organisms. Loew, who thinks that the presence of peritoneal, mesenteric, or other ill-defined symptoms suggests too seldom the possibility of intestinal parasites, has recorded a case of epileptiform convulsions in a soldier which were wrongly attributed to absinthio, whereas the real cause was a tapeworm.

177 Subacute Endocarditis and Syphilis.

Of 52 cases of subacute endocarditis (endocarditis lenta) observed during the years 1919-27, J. SUMBIL (*Pratis. vst. i. Istarske Listy*, May, 1928, p 267) found in 18 instances a positive Wassermann reaction. He believes that the reaction in these cases is due to a previous syphilitic infection. He remarks that in subacute endocarditis, which is really a chronic septicaemia, the entire cardio-vascular system is affected as a manifestation of disease of the reticulo endothelial apparatus. The syphilitic infection, by reducing the defensive powers of the reticulo-endothelial apparatus, prepares the way for the subacute endocarditis. Endocarditis on a syphilitic basis is characterized by manifesting a tendency to a haemorrhagic diathesis, to a protracted course with a low temperature curve, and to improvement under the influence of antisyphilitic treatment. In cases where the endocarditis occurs soon after the syphilitic infection, or where it complicates an already existing syphilitic infection, the antisyphilitic treatment is more liable to fail or even to exacerbate the condition. It is suggested that the increased number of cases of subacute endocarditis following the war is probably due to the increase of syphilitic infection. Sumbil advises systematic examination of the blood by the Wassermann test in all cases of cardiac diseases, irrespective of their origin, and even when there is complete compensation, since an existing syphilitic infection influences unfavourably the prognosis of the cardiac disease owing to the possibility of the appearance of a subacute endocarditis.

178 Immunity of Newborn to Scarlet Fever

A. LICHTENSTEIN (*Acta Paediatrica Supplement*, April 20th, 1928, p 121) performed the Dick test on 100 recently delivered women and their children, with the following results: (1) 27 per cent. of the women were positive and 73 negative, (2) of the newborn children only 7 per cent were positive and 93 per cent were negative. (3) the children of Dick negative mothers always gave a negative reaction, but of 27 Dick positive mothers only 7 had positive children, while the remaining children (about three quarters of the total) were Dick negative. The following results were obtained from Schmitz-Charlton tests. Serums from Dick negative puerperal women had regularly the power of extinguishing a scarlatinal rash. Blood from the umbilical cord of children of Dick negative mothers also consistently produced extinction. Serums from Dick positive puerperal women lacked extinguishing power. Blood from the umbilical cord of children of Dick positive mothers also had no power to produce extinction even in cases where the children were Dick negative. Lichtenstein concludes that the newborn child is not susceptible to scarlet fever because the body is not yet able to react to scarlatinal infection with the development of a typical scarlatinal complex. Present knowledge of the immunity to scarlet fever is quite compatible with the view that the disease is an anaphylactic process.

179

The Dick Reaction

N. MALDIBLIG and G. JACOBSON (*Acta Paediatrica*, Supplement, April 20th, 1928, p 119) investigated the Dick reaction in 1,200 children from birth to 15 years of age, and found that it was positive in 66.8 per cent., negative in 24.2 per cent., and doubtful in 9 per cent. In children with a previous history of scarlet fever the reaction was positive in 11 per cent. Pseudo-reactions were more frequently found in children with increased sensitivity to tuberculin than in those without. Investigations of the spontaneous validity of the Dick reaction showed that in the case of a positive reaction there were practically no changes on re-testing, whereas a negative reaction changed into a positive one in 20 per cent. The authors conclude, therefore, that a positive reaction may be regarded as giving definite information, whereas a negative one should be considered more cautiously and the patient should be re-tested.

180.

Pain in Duodenal Ulcer

M. J. WILSON (*Arch Intern Med*, May, 1928, p 633) describes an investigation into the cause of pain in duodenal ulcer. A brief account is given of the numerous explanations advanced, such as mechanical irritation by coarse particles of food, spasm of the pyloric or duodenal musculature, and the action of acid gastric juice on the sensitive nerve endings in the ulcer base. The acid theory is called in question by the work of Hurst, who introduced 0.5 per cent. hydrochloric acid into the stomachs of six patients with gastric ulcer, producing no sensation whatever. Observations on the role of muscular activity have been conflicting, while the theory of mechanical irritation must be doubted in view of the relief of duodenal ulcer pain by alkali or food. The author has made x-ray examinations of sixteen patients with duodenal ulcer suffering from pain at the time of observation. The opaque meal was given and the period elapsing before the onset of pain noted. When pain started the patient was examined by the fluorescent screen. Part of the lumen was observed to be still in the stomach, and it was found that with practice the stomach contents could be manipulated through the pylorus and be made to fill the duodenal caput. In thirteen of the cases this procedure was followed by almost immediate relief of the pain, persistence of pain in two of the remaining cases was attributable to postural abnormality of the stomach. It is inferred from these investigations that duodenal ulcer pain is not directly related to acidity or gastric peristalsis, and that such pain is due to sustained contraction of the duodenal caput, since it is relieved by filling this part of the bowel with gastric contents.

181 Paroxysmal Oculogyric Crises in Parkinsonian Encephalitis

I. PARDEL (*Amer Journ Med Sci*, May, 1928, p 683), who records four illustrative cases in patients aged from 13 to 27, states that there have recently been an increasing number of references in foreign literature to an eye syndrome which differs from that previously described, in that it appears late in the disease, is perhaps preceded by no previous eye symptoms, and is almost invariably a sequel of the Parkinsonian syndrome. This syndrome consists in hypertonic paroxysms of conjugate deviation resulting in forced movements upwards, which are frequently accompanied by other torsion phenomena. Its occurrence suggests a striatal, gondri-geminal body posterior longitudinal fasciculus complex as the underlying cause of the condition. The immediate cause of the paroxysms seems to be fatigue, emotion, metabolic accumulation, and focal absorption.

182

The Haemorrhagic Diathesis.

V. FANANO (*Il Politecnico, Sez Med*, May 1st, 1928, p 255) publishes three cases of haemorrhagic diathesis in children, illustrating the chief features of this condition. In each case there was haemorrhage from the mucous membranes and skin, spontaneous in origin, recurring and unassociated with any of the numerous causes of secondary purpura or with haemophilia. The blood showed thrombopenia, irretractability of the clot, and great diminution of platelets, those present being abnormally large and having a poor staining capacity. There was prolongation of the "dripping time" of the blood drop and a positive reaction to the ligature test (appearance of petechiae below the ligature) and other similar tests. The coagulation time *in vitro* was not much altered. In those cases Fanano thinks that a delicacy of the capillaries must be assumed, it is constitutional in origin, and tends to have long latent periods, but is easily aroused.

by the many stimuli which may induce a haemorrhagic crisis. Haemophilin could be excluded in the author's cases by the absence of any heredity, the spontaneous character of the haemorrhage, and by the normal coagulation.

133 Well's Disease following Trauma

H. A. LAMPE (*Nederl. Tijdschr. v. Geneesk.*, June 2nd, 1928, p. 2653) records the case of a man, aged 23, who injured the tip of his little finger with a reed while standing knee deep in ditch water. A few days later a whitlow developed, followed by high fever, jaundice, and a scarlatiniform rash. The serum agglutinated *Leptospira icterohaemorrhagiae* in a dilution of 1 in 5,000, and inoculation of a guinea pig with the virus gave a positive result. Recovery gradually followed, and the patient was able to resume work after three months. Lampe considers that the wound in the finger formed the point of entry for infection with the leptospira in the ditch water.

184. Acidosis in Methyl Salicylate Poisoning

J. G. M. OLMSTED and O. A. ALDRICH (*Journ. Amer. Med. Assoc.*, May 5th, 1928, p. 1438) report two cases of methyl salicylate poisoning in children; they have also collected records of twenty-four instances of this form of poisoning. Vomiting and abdominal pain occurred in most cases owing to the local irritant action of the drug on the alimentary canal. The most remarkable symptoms in the authors' cases were hypopnoea, flushed skin, coma, and convulsions. These symptoms the authors attribute to acidosis, and they show that symptoms of acidosis were present in most of the recorded cases of poisoning. Treatment with alkalis (sodium bicarbonate, 1 gram hourly) rapidly produced relief and cure in both cases, although the children appeared at first to be in a desperate condition.

185 Pulmonary Embolism Complicating Sciatica

A. THYSEN (*Ugeskrift for Læger*, April 26th, 1928, p. 381) records five cases of sciatica complicated by pulmonary embolism; in four cases there was phlebitis of the femoral vein. After giving details of the cases, the author asks, Is the phlebitis in such cases due to the obstruction to bed, or to the massage prescribed for the sciatica? May a condition diagnosed as sciatica in reality be a deep-seated phlebitis without a rise of temperature or oedema? Or may a sciatica be due to an infection predisposing to phlebitis?

Surgery.

186 Surgical Treatment of Exophthalmic Goitre.

L. BERARD and DUNET (*Presse Méd.*, June 13th, 1928, p. 737) suggest that insufficient importance has been attached to the surgery of this disease in France, and emphasize the value of co-operation between the physician and the surgeon in its successful treatment. The principles of modern treatment should be accurate diagnosis by clinical investigation and study of the basal metabolism, distinguishing true exophthalmic goitres from toxic thyroid adenomata, general hygienic measures, including rest, hydrotherapy, and diet, and sedatives, cardiac tonics, electrical treatment, and serums. Quinine and quindine are specially mentioned as useful, but the authors consider iodine the most important remedy, and prefer to give it in the form of Lugol's solution. They distinguish three groups of cases: (1) exophthalmic goitres with complete Basedow syndrome, but with compensated heart and little general toxæmia, (2) severe forms with a fibrillating uncompensated heart, and (3) very grave cases with meningeal toxic symptoms, such as nystagmus, nausea, and persistent diarrhoea. The increase of basal metabolism is mentioned as an important point in the consideration of the type of, and suitability for, operation. In Group (1) thyroidectomy can be performed at once after treatment with small doses of iodine for a fortnight under medical care, attention being given to rest and diet. Lugol's solution in 10 minim doses is given three times a day, twice before meals and once at 9 p.m. If the basal metabolism is not more than 25 per cent above normal the operation is performed under a regional or general anaesthetic. A brief description of the most suitable form of operation is given and the importance of immediate and remote treatment is emphasized. In Groups (2) and (3) the general technique is the same, but preparatory treatment must be continued for a longer period. In cases of oedema or nystagmus, diuretics and digitalis should be given. Operative treatment is performed in stages. First, one or two thyroid arteries are tied, and medical treatment is continued until the direct intervention on the gland is permissible. The authors give statistics of nearly 100 cases of exophthalmic goitre operated upon by them during the last fifteen years. There were

three deaths in the period before preoperative medical treatment was so methodically conducted, but for the last four years no death has occurred. Since performing a larger number of early subtotal thyroidectomies after previous iodine treatment post-operative accidents have been more and more reduced and the results have continuously become more satisfactory.

187 Temporary Ligature of the Common Carotid for Haemorrhage following Tonsillectomy

A. H. HOFMANN (*Centralbl. f. Chir.*, May 26th, 1928, p. 1292) removed the hypertrophied right tonsil in a patient aged 21, and intractable haemorrhage followed, digital and intraoral compression for five hours being unavailing. On discontinuing this compression the haemorrhage became more copious. The bleeding vessel could not be secured with artery forceps, nor was the haemorrhage arrested by posture. The patient had lost at least two and a half pints of blood and was very pale and exhausted. It was therefore decided to ligature the external carotid. The artery was exposed at its origin, and a ligature was passed around it, but when tightened it did not arrest the bleeding. When, however, the common carotid was compressed by the finger, the arterial haemorrhage ceased. A broad silk ligature was passed around the common carotid and tightened over a small swab sufficiently to arrest the haemorrhage, no cerebral symptoms followed. Three days later the ligature was divided and the swab removed. The constriction in the arterial trunk disappeared immediately. Apparently the ligature, being tied over a swab (thus imitating digital compression), prevented any injury to the intima. There was no sign of embolism. Hofmann believes that the bleeding vessel was an aberrant branch of the internal carotid; this would explain the failure of temporary ligature of the external carotid.

188. Intestinal Obstruction Simulated by Gas Accumulation

ACCORDING to G. LEYEN (*Bull. Soc. de Théor.*, March 14th, 1928, p. 97), who records three illustrative cases, the accumulation of gas in the colon may cause a form of intestinal obstruction of which the diagnosis is simple and the treatment purely medical. He believes that the general ignorance of the condition, alike by physicians and surgeons, has been responsible for numerous needless operations for appendicitis or intussusceptions of abortion for vomiting in pregnancy. It is added that the existence of the intestinal obstruction from accumulation of gas in the colon has been proved by radiological examination as well as by the results of treatment. Examination of the patient shows the clinical picture of aerophagia—namely, a red, moist, shining tongue, profuse salivation, which is most marked at night, abnormal tenderness of the larynx due to frequent swallowing caused by the excess of saliva, and an abnormal prehepatic resonance owing to distension of the colon. The patients can sleep on their right side only, since the distension of the stomach gives rise to painful cardiac sensations as soon as they lie on their left side. Treatment consists in making the patients perform successive movements of prolonged expiration as in blowing out a candle, putting them in a very hot bath, or in passing a catheter into the stomach. The use of one or more of these methods causes an escape of intestinal gas and is followed by rapid recovery, the abdominal distension subsiding, the dyspnoea ceasing, and the pulse becoming normal.

189 Primary Adenocarcinoma of the Duodenum

J. D. DEWIS and G. W. MORSE (*New England Journ. Med.*, April 12th, 1928, p. 383), who record twelve cases with a review of the literature, come to the following conclusions. Duodenal cancer usually occurs in the sixth decade of life, the youngest patient recorded was aged 23. It probably develops independently, and there is little evidence that it ever arises in pre-existing benign duodenal ulcers, the obstructive symptoms caused by it are more rapid in onset than are those of pyloric cancer. Primary cancer of the duodenum usually obstructs the gut, primary cancer of the pylorus seldom blocks the bowel. An abrupt incidence of gastric stasis in middle age suggests duodenal cancer, and the diagnosis is confirmed by the absence of free hydrochloric acid in the stomach. Bile will be found in the gastric contents when the duodenal constriction is below the ampulla of Vater. Blood is present in the stools in cancer of the duodenum except in scirrhus cancer without ulceration. Perforation at the site of duodenal cancer may cause the first symptoms. Perforation of a duodenal ulcer is suggestive of cancer, especially in persons over 60. Metastases in duodenal cancer are not frequent, they were found in only three of the authors' cases. Syphilitic ulceration and cancer of the duodenum may be associated with symptoms and laboratory findings hardly distinguishable by present methods. Gammata rarely occur in the duodenum, but not so rarely

in the jejunum and ileum. X rays may aid in the diagnosis, especially in the absence of obstruction. It may not be possible at operation to distinguish simple ulcers from early cancer of the duodenum. In such cases it is best to excise the lesion.

190. Treatment of Cholelithiasis in Elderly Patients

L. METZLER (*Wien Klin Woch*, May 17th, 1928, p. 689) has analysed in detail the histories and results of treatment in 45 patients over 60 years of age suffering from cholelithiasis. The operative mortality in the 25 cases treated between acute attacks was 8 per cent, while of 20 in whom immediate operation had to be performed during an acute attack because of jaundice, high temperature, or symptoms of peritoneal irritation, 44.1 per cent died, the total operative mortality being 24 per cent. One-half of the patients had been ill for more than a year, and in one instance the duration of the illness prior to operation was over forty years. His analysis has led Metzler to the conclusion that the high mortality after operations on the gall bladder, particularly in elderly patients, is more often due to a long history of repeated acute attacks treated medically with temporary improvement, and to the damage to the liver and other organs (and consequently to the general health) associated with chronic cholecystitis, than to the actual age of the patient at the time of operation. Even in these elderly patients who give only a short history he advocates early operation, preferably in an interval after an acute attack has subsided, since this allows for adequate preparation. He considers that local anaesthesia, limiting drainage to a minimum, and careful after-treatment further improves the prognosis. In non-complicated cases patients were allowed out of bed as early as the day of the operation, apparently with beneficial results.

191. Purulent Meningitis Cured by Operation

P. C. SIMONS (*Nederl Tijdschr v Geneesl*, May 26th, 1928, p. 2559), who records an illustrative case, remarks that recovery from meningitis of nasal origin as the result of operation is very rare. According to H. Burger, who mentions only one successful case, the prognosis is very unfavourable. Simons's patient was a previously healthy man, aged 46, who a few days after a severe attack of tonsillitis developed infection of both frontal sinuses, followed by symptoms of meningitis. Killian's operation was performed followed by four lumbar punctures, 10 to 20 c cm of turbid fluid being removed on each occasion. An intravenous injection of 10 c cm of a 1 per cent solution of trypanflavin was given on two occasions, and probably contributed to recovery, which followed in about three months' time. It was significant that the organisms found in the cerebrospinal fluid were not the ordinary pyogenic bacteria such as streptococci, staphylococci, pneumococci, or meningococci, but diplococci and tetrads.

192. Appendicitis in Measles.

F. ROST (*Zentralbl f Chir*, April 14th, 1928, p. 905), who records an illustrative case, states that the association of appendicitis and measles is a rare occurrence of which no mention is made in surgical and paediatric textbooks, while the cases reported by Gottstein and Kuttner (*ibid.*, 1927, p. 2095) are the only cases on record known to him. Rost's patient was a girl, aged 4, who six days after the onset of measles, while the eruption was still well marked, developed symptoms of appendicitis. The child was kept under close observation, and operation was not performed until the twelfth day, when a circumscribed abscess was felt in the appendix region and evacuated. Recovery was complete ten days later.

193. Treatment of Ganglion on the Back of the Hand.

I. EISENKLAM (*Wien Klin Woch*, May 24th, 1928, p. 740) describes the following method, which has been employed for several years at the first surgical department of the General Hospital at Vienna in preference to all other methods, such as crushing and extirpation. A large sized Pravaz needle is driven through the ganglion so that the point can be felt beneath the skin on the opposite side. The needle is then withdrawn nearly up to the point of insertion and then plunged in various directions five or six times, or even as many as ten, care being taken that the parts surrounding the young cysts are perforated. On removing the syringe some of the contents of the cysts can be evacuated by gently pressing the skin, but most of the contents escape into the surrounding tissue, just as after the crushing method. Not infrequently a permanent cure is effected by a single application of this method, but in the case of recurrence the procedure can be repeated without waiting till the ganglion regains its former size. This method is said to be less painful than crushing and does not interfere with the patient's occupation.

Therapeutics.

194. Treatment of Nausea and Related Circulatory Sensations.

R. W. KEETON and ESTHER S. NELSON (*Journ Amer Med Assoc*, March 3rd, 1928, p. 683) have studied experimentally the control of nausea and certain closely related sensations, including dizziness, lightness of the head, mental numbness, pressure in the head and neck, and headache, their direct relation to vomiting having been previously shown by Keeton. As the result of their experiments they have found that the reflexes involved must first be disorganized or separated from their central connections, after which a mild cathartic will re-establish the arrested intestinal peristalsis. During the last four years they have used a powder containing 1 gram of disodium phosphate, 1 gram of sodium bicarbonate, and 1 gram of sodium bromide, or an equivalent bromide mixture. This powder is dissolved in 100 c cm of water and given on an empty stomach. It has resulted in symptomatic relief in a wide variety of conditions. In the milder cases of nausea of pregnancy the powder is given forty-five minutes before each meal. In some cases of migraine it has been possible to give one, two, or three doses at forty-five minute intervals, thus lessening the headache and obviating vomiting. The powder is said to have proved of great value in controlling the dizziness and pressure headaches in cases of non-ulcerative colitis, and in colitis secondary to low grade pyelitis. It has been used occasionally in acute exacerbations of blood pressure when the patient was disturbed by dizziness and mental numbness. Sodium bromide in practice was usually replaced by a less deliquescent mixture of the sodium, potassium, and ammonium bromides in equal parts. Paraldehyde acted less effectively when vomiting was present. In cases of pronounced nausea the patient received only half a powder at the first dose, when necessary a second and third dose were repeated at intervals of forty-five minutes. It was found that an increase of above 1 gram of the disodium phosphate tended to make patients more nauseated and sometimes caused vomiting. When the circulatory sensations were primarily concerned the dose of bromide was increased and the phosphate slightly reduced.

195. The Specific Treatment of Syphilitic Aortitis

E. DOUVER (*Bull et Mém Soc Méd des Hôp de Paris*, May 31st, 1928, p. 853) discusses the treatment of syphilitic aortitis by injections of arsenobenzol and bismuth. Although these drugs often give good results, ill effects are liable to follow their use, especially in the case of arsenobenzol. For example, if there are but slight signs of cardiac failure they are likely to be increased, while if anginal attacks have been experienced greater severity and frequency of attacks may result. Such accidents arising in the course of treatment have been regarded as manifestations of reactivation of the syphilitic infection, and they have been compared with the Herxheimer reaction. The latter is clearly due to renewal of activity, but certain features of the complicating congestive and anginal failure show them to be of different origin. Thus cardiac vascular disturbances generally occur after the third or fourth injection when the dosage is being increased, and the patient's condition progressively deteriorates until treatment is suspended. On the other hand, Herxheimer's reaction follows the earlier injections, and the accompanying eruption disappears despite the continuance of treatment. Furthermore, the circulatory embarrassments are observed with doses that usually exert a curative influence on cutaneous lesions and gummatous, and at a stage when improvement is ordinarily resulting. In explanation of these undesirable phenomena it has been suggested that they depend upon the irritation provoked by vascular congestion which attends resolution of gummatous infiltration and the absorption of necrotic material. If signs of cardiac vascular disturbance appear it is necessary to discontinue injections at once, and subsequently to give smaller doses over a more prolonged period, or to substitute bismuth for arsenobenzol, or even to rely solely upon the use of mercury and potassium iodide.

196. Contraindications to the Use of Salvarsan

J. GATÉ and P. BARRAL (*Journ de Med de Lyon*, May 20th, 1928, p. 283) state that in the course of secondary syphilis, in addition to coincidental jaundice such as cholelithiasis or ordinary infective jaundice other forms of jaundice may develop, such as the so-called prereseolar jaundice, simple jaundice, and even icterus gravis. Haemolytic jaundice is rare. Moreover, since the introduction of arsenical preparations the number of cases of jaundice occurring in syphilis has shown a considerable increase. Most of them may be regarded as toxic, but some are due to syphilis and constitute an herpetic Herxheimer reaction. The practical conclusions are as follows: (1) Salvarsan is contraindicated in the presence

of any jaundice occurring in a syphilitic patient even when no treatment has been applied. (2) As it is impossible to say whether jaundice occurring in the course of salvarsan treatment is toxic or syphilitic, it is best to continue with anti-syphilitic treatment but to replace salvarsan by intravenous injections of mercury cyanide, which is the least likely drug to injure the hepatic cells. Bismuth, owing to its possible toxicity, is contraindicated. (3) The significance of jaundice occurring after salvarsan treatment varies in different cases. If the treatment has been very energetic and sufficiently prolonged, and there has been no other sign of active syphilis as well as a negative Wassermann reaction, the symptomatic treatment of jaundice is all that is necessary. If, on the other hand, there is reason to suppose that syphilis is responsible, treatment by mercury cyanide exclusively should be adopted.

187 Malariotherapy in General Paralysis

A. MO (*La Med Ibera*, June 2nd, 1928, p. 621) during the last five years has treated 85 cases of general paralysis by direct simultaneous inoculation of malarial blood. The quartan form was always used, as it is more readily affected by quinine and is followed by a longer period of apyrexia than the tertian form. The incubation period after simultaneous inoculation varied, and might be as long as thirty nine or forty days, but was usually between fifteen and twenty days. The patient was kept under close observation during the febrile attacks, of which fifteen or sixteen were allowed to occur if the general condition permitted it. In debilitated patients 10 to 15 cc of quinine were injected to cut short the attacks, whereas if the attacks were ill marked they were rendered more violent by the simultaneous injection of adrenaline. When the malariotherapy was completed antisyphilitic treatment was instituted. The results were as follows. Of the 85 patients, 28 (31.46 per cent) made a complete recovery and were able to resume their occupation, 11 (12.35 per cent) showed considerable improvement without being able to resume their occupation, 14 (15.75 per cent) showed slight improvement, and 32 (33.84 per cent) showed no change. The total number of deaths since treatment had started was 14 (14.60 per cent).

188 Treatment of Epilepsy

In a review of epilepsy from the standpoint of physiology and therapeutics W. G. LENOX and S. COBB (*Medicine*, May, 1928, p. 105) discuss its specific treatment and emphasize the importance of careful attention to general hygiene and diet. It is suggested that as a first line of defence against attacks the patient should be helped to maintain peace of mind in a fully healthy body. The authors disagree with the practice of excluding fresh fruits from the diet on the ground that they are acid forming, and deny that there is need in epilepsy to guard against acidosis. In the evidence they have accumulated there appeared to be no justification for this view, and they therefore recommend simple and nutritious feeding, but not in excess of that necessary to satisfy caloric requirements. A ketogenic diet is indicated in children when the seizures are so frequent as to justify the inconvenience caused by it. Bromide treatment, with a restricted constant salt intake, has been found most effective in diminishing the number of fits, though luminal has displaced bromide to a large extent because it is less depressant. The usual dose employed is 1½ grains daily, and luminal sodium, being more soluble, can be given subcutaneously or intravenously. Levi has reported that the intravenous injection of 5 grains of luminal sodium in three patients with status epilepticus brought the fits to an end almost immediately, and the present authors mention a case in which a single intravenous injection of 10 grains of luminal sodium completely suppressed fits for a period of four days in a patient who had previously had fifteen to twenty of these daily. With status epilepticus, in addition to drainage of the spinal fluid, the inhalation of a mixture of 10 per cent carbon dioxide and 90 per cent oxygen is suggested. Magnesium sulphate, given by the mouth in a 50 per cent solution, serves to reduce intracranial pressure, increase acidosis, and clean out the bowels. The warning is given that in some patients the use of sedatives appears to damp up the fits which are subsequently released in a flood when the control of the sedative is relaxed.

189 Intraperitoneal Dextrose Injections

R. N. SANFORD and P. L. HEITMEYER (*Journ. Amer. Med. Assoc.*, March 10th, 1928, p. 737) discuss the value of intraperitoneal injections of dextrose in the treatment of certain diseases of children; they describe a method of dry sterilization which obviates reactions and overcomes the tendency to acid formation. Five grams of chemically pure dextrose are placed in a pyrex tube 150 by 20 mm and thoroughly dried by hot blast and baking for forty minutes at 100°C. The tube is then plugged by inserting a piece of gauze of four

thicknesses, 20 by 20 cm., over the top and pushing it down into the bore for about 10 cm., into this cavity about 5 grains of anhydrous chloride are placed. After autoclaving for twenty minutes at 15 lb. pressure the tube is ready for use and will keep for at least fourteen days, but it should not be used if any brown spots are seen in the dextrose or if there is moisture in the plug. By the addition of 100 c. cm. of twice distilled water to the dextrose a 5 per cent solution is obtained for intraperitoneal injection. A higher concentration than this is contraindicated because of the tendency to draw body fluid into the abdominal cavity. Since uniformly successful results followed this treatment in cases of toxæmia with dehydration its use was extended to the treatment of any disturbance due to insufficient nourishment, marasmus, pneumonia, pyelitis and post-operative conditions. These intraperitoneal injections were never given in larger quantities than 100 c. cm. at one time, but in order to be effective they require frequently repeating at about twelve hourly intervals, one child received six daily for four days. The authors add that by their method of dry sterilization such injections can be given without any resulting reactions.

Ophthalmology.

200 A Racial Factor in the Etiology of Myopia.

A. SOBRASKI (*Brit. Journ. Ophthalmol.*, April, 1928, p. 197) has investigated the incidence of visual defects in Jewish children in the East End of London and compared them with those found in non-Jewish children. He reports that myopia is twice as common in Jewish as contrasted with non-Jewish boys. This myopia does not seem to be induced by the greater amount of close work (Hebrew classes) which the Jewish boys do. It appears rather to be due to the fact that the Jewish boy normally has a lower hypermetropic reserve than the non-Jewish boy. There is always a tendency during adolescence for a move away from hypermetropia towards myopia. In Jewish boys the incidence of myopia is greater in the later years of school life because they are deficient in hypermetropic reserve, and so their myopia becomes more easily developed. It also appears that the incidence of myopia among Jewish boys is much greater than among Jewish girls. This also holds good for the non-Jewish boys and girls, but whereas the Jewish boys do a great deal more close work than the Jewish girls, this is not the case among the non-Jewish boys and girls. Sobraski's statistics suggest that excessive close work is not so important a factor in the development of myopia as has been previously thought. During adolescent growth there is a general tendency towards myopia which demands in early adolescence a hypermetropic reserve, and in this the Jews are defective. He suggests that this hypermetropic reserve is a racial factor. The adolescent tendency towards myopia is equally common in boys, Jewish or non-Jewish, but is much less marked in girls. This appears to be a sex-determined factor.

201 Gangrenous Peridacryocystitis

R. DEL CASTILLO RUIZ (*La Med Ibera*, March 17th, 1928, p. 287), who records a personal case, illustrates the rarity of this condition by the fact that he has been able to find only three other examples on record reported by Vellou and Morax, Couge, and Jost respectively. In Jost's case the affection was bilateral. The patient of Ruiz was a woman aged 23, who after suffering from epiphora in the right eye for two years, developed acute suppurative peridacryocystitis. The abscess opened spontaneously and gave issue to a large quantity of foetid pus. Two days later a black slough formed, extending from the internal canthus to half way along the margin of the lower lid. There was no glandular enlargement. The temperature was 102.2°, and the patient was in a condition of prostration. The gangrenous area was treated with Paquelin's cautery under chloroform and the wound packed with iodoform gauze. Two doses of anti-gangrene serum were given and complete recovery followed.

202. Conjunctivoplasty in Corneal Affections

J. GREEN (*Amer. Journ. Ophthalmol.*, January, 1928, p. 12) advocates the use of a conjunctival flap or covering in certain corneal conditions. He has found it especially valuable in marginal ulcer, obstinate pannus, scirrhous nodule, descemetic perforation of the cornea, and Mooren's ulcer. Green considers that this method is not employed so often as it might be. The flap usually retracts back from the cornea after about four days. Green believes that the conjunctival flap subserves several purposes. It controls pain by covering up the exposed sensory nerves, and it protects the bare corneal surface, the fern from the vessels of the flap forms a non-irritating film which aids repair of the corneal lesion.

Obstetrics and Gynaecology.

203. Cervico vaginal Fistula

ACCORDING to P. CALLIFER (*Zentralbl. f. Gynäk.*, May 12th, 1928, p. 1206) central rupture of the cervix, although it may occur spontaneously in abortion, has become more common lately as an accompaniment of criminal induction of premature birth. It may be compared anatomically with central rupture of the perineum, with delivery of the presenting part through the new opening instead of the vulva. A tear having occurred in the wall of the cervix, abortion follows through the tear instead of the external os. The immediate consequences of central rupture of the cervix are seldom serious, although occasionally bleeding may necessitate insertion of a suture. The remote sequel is usually the production of a cervico vaginal fistula, through which, instead of the external os, menstruation and parturition chiefly take place. Spontaneous healing of such a fistula has been recorded, but appears to be unusual, commonly, as in a case described by Callifer, the cervical tissue connecting the fistula and the external os breaks down during subsequent deliveries, so that the rupture and the os unite to form a common orifice. Predisposing causes of spontaneous rupture of the cervix are extreme anteversion of the uterus and rigidity of the cervix, both these factors were present in a case now described, in which abortion was induced in hospital during the third month on account of uncompensated mitral stenosis. Insertion of a balloon having failed to complete dilatation of the cervix, a laminaria tent was introduced and the vagina plugged. Next day the tent was found still occluding the cervical canal, but the foot was in the vagina, having been delivered through a spontaneous rupture of the posterior wall of the cervix. The placenta was still in the uterus, and the umbilical cord, passing through the rupture connected it with the foetus. In a second case described by Callifer abortion was probably self induced in the fourth month, and was attended with fever on admission to hospital. The rupture was not diagnosed until introduction of a speculum with a view to enrolling. It was then found that the impossibility of expressing the foetus by pressure on the fundus was due to a sort of impaction of the trunk in the rupture, the feet lay in the vagina, the breech in the cervix, and the head, together with the placenta in the posterior vaginal fornix. In this case arterial bleeding necessitated stitching of the margins of the tear.

204. Clinical Use of Ovarian Follicular Hormone.

J. C. HIRST (*Am. Journ. Obstet. and Gynecol.*, April, 1928, p. 487) describes his experience and that of Pratt and Allen with regard to the clinical use of ovarian follicular hormone. Hirst gave intramuscular injections of fresh lipid extract of liquor folliculi or a similar preparation of placental derivation, commercial preparation of the hormone is stated to be still in an experimental stage. From the ovary it has been obtained in a concentration representing 15 Allen and Dofsy rat units per cubic centimetre, but this involves an inconveniently large consumption of gland, practically a preparation made from placenta in greater concentration seems more useful at present, and this was used in many of Hirst's patients. From three to ten injections were given in ten days, and 25 to 250 rat units in each series. Five patients were treated for menstrual disorders. No change was noted in a woman, aged 29, suffering from secondary amenorrhoea and obesity, or in a girl, aged 14, who had only menstruated once at the age of 10. Normal menstruations followed treatment in (1) a patient, aged 24, with retarded scanty periods, (2) a girl, aged 16, with dysmenorrhoea every eight weeks, (3) a woman, aged 34, who after an intrauterine radium application for metrorrhagia had "showing" only on four occasions during sixteen months. Hirst also treated twelve cases of sterility. Six were associated with marked reduction of menstruation, all became improved and three subsequently conceived. Of the six patients without menstrual reduction two conceived. In Pratt and Allen's clinical observations 15 to 90 rat units failed to modify cases of primary amenorrhoea but some response was shown in cases of scanty menstruation, of artificial (operative) menopause, and of functional climacteric symptoms.

205. The Results of Operations for Cancer of the Uterus

G. SCHAANNING (*Tidsskrift f. d. Norske Lægeforening*, June 1st, 1928, p. 505) has collected the records of the cases of cancer of the uterus admitted to the University Gynaecological Clinic in Oslo between 1906 and 1925—a total of 562 cases. In 508 the cervix and in 54 the body of the uterus was involved. The subsequent fate of 537 patients was ascertained, in only 25 instances was it impossible to trace the patients. Of the 508 cases of cancer of the cervix, 287, or 56.5 per cent, were operated on, a radical

operation being performed in 226 cases, or 44.5 per cent. The operative mortality for all the operations for cancer of the cervix was 10.6 per cent (24 deaths out of 226 operations), it varied greatly according to the extent of the disease and the increasing operative dexterity in the hospital. Thus it was only 7.3 per cent in the cases in which the cervix alone was infiltrated, whereas it was 15.7 per cent in the cases in which the parametrium was involved. In the five year period 1906 to 1910 it was 21.4 per cent, whereas in the period 1916 to 1925 it was only 5.6 per cent, although in the meantime the hospital had not made its indications for operative intervention more exclusive. The author publishes a table in which he gives the proportions of patients surviving the operation by five years without a relapse, classifying them according to the degree of involvement at the time of the operation. When only the cervix was involved, and there was no glandular infiltration, the survival rate without recurrence after five years was 33.8 per cent, whereas it was only 26.7 per cent for all the cases of cancer of the cervix submitted to a radical operation. With regard to the cases of cancer of the body of the uterus, the total operative mortality was 8.3 per cent, being 10.7 per cent for cases operated on by the abdominal route and 5.5 per cent for those operated on by the vaginal route. But the ultimate results after a 5 year interval were much better for the abdominal route, 73.3 per cent of the patients thus operated on being still alive, whereas this was the case with only 40 per cent of the patients operated on by the vaginal route, which does not allow of such extensive removal of cancer infiltrated tissues. The author concludes that the most important means by which the prognosis for cancer of the uterus can be improved is a continuous campaign of enlightenment of the general public.

206. Malignant Disease of the Vulva.

N. R. MASON (*New England Journ. of Med.* May 24th, 1928, p. 727) reports a case of malignant disease in the vulva, and refers to another case of the same kind recorded by him four years ago. In each instance removal of the growth was performed with vulvectomy and excision of the glands, and no recurrence has as yet been detected. The growth was carcinomatous in both cases, and is attributed to chronic irritation of the vulva, in one patient apparently following a warty growth of unknown nature. The author remarks that epithelioma of the vulva starts usually as a small hard nodule on the lower portion of the labium majus, which develops slowly and at first causes no symptoms apart from occasional troublesome itching, later an ulcer appears, surrounded by an indurated area, associated with a watery discharge which is sometimes mixed with blood. The subsequent progress of the growth is rapid. Mason emphasizes the importance of careful examination of indurated tissue discovered in this neighbourhood or near the urinary meatus. Two years is given as the usual duration of the disease. Wide surgical excision of the growth is necessary, except in cancer of the urethra and of the clitoris close to the urethra, in these two conditions radium treatment is recommended, since it does not usually destroy the urethral function. The operation may be preceded by radium application and he followed by x ray therapy.

207. Support of the Perineum

O. SEYNSCHE (*Zentralbl. f. Gynäk.*, May 26th, 1928, p. 1311) agrees with those German obstetricians who, with a view to the prevention of utero vaginal prolapse, have recently pleaded for modification of the custom by which during the delivery of the foetal head the attention of the midwife is chiefly centred on "supporting the perineum." Such support has been thought to diminish the incidence of perineal tears and the liability to subsequent occurrence of cystocele, rectocele, and prolapse. It is doubtful, however, whether the first object is secured, and there is some evidence that "supporting the perineum" actually defeats the second. In consequence of delay of the head, anaemia and mechanical injury of the muscular and elastic tissue of the pelvic floor are prolonged, so that utero vaginal descent after childbirth is favoured. In the author's opinion the procedure now employed in normal labours differs according to the degree of distensibility that is noted in the perineum. If it is readily distended spontaneous delivery is allowed without special support of the perineum, and any tear that occurs is stitched. If the perineum is resistant and delivery is thereby retarded it is split during the height of a uterine contraction by a mesial incision, which may extend as deep as the levator ani, and the head is delivered slowly and with the most persistent flexion during ethyl chloride anaesthesia. It is conceded that by this means tears of the levator are not always prevented, but it is argued that exact suture of these is a sure way of preventing cystocele, rectocele, and prolapse. It is said that, in hospital at any rate, the occurrence of a perineal tear does not predispose to puerperal infection.

Seynscho adds that to teach the midwife in extern practice to attach less importance to "supporting the perineum" is in the first instance fraught with difficulties, for the occurrence of tears is popularly thought to be a cause of reproach, and, in practice, more numerous tears will increase the expense of accouchements.

208. Perforation and Rupture of Pyosalpinx

J L LAPEYRE (*Gynéc. et Obstét.*, April, 1928, p 304) reports two cases of acute general peritonitis, the one consecutive to a rupture, and the other to a perforation, of a pyosalpinx. In each case the treatment adopted was drainage, as recommended by Mikulicz after subumbilical laparotomy. In the first case the rupture of the pyosalpinx occurred in a woman aged 40, and was caused by a fall. An operation was performed within thirty-six hours, and the patient recovered. In the second case the perforation of the pyosalpinx was spontaneous. Operation was undertaken within sixteen hours, and was followed by recovery. Bacteriological examination of the pus revealed the presence of *B. coli* only. The author remarks that these two cases indicate the difference between rupture of a pyosalpinx which is traumatic in origin, and perforation of a pyosalpinx which is inflammatory in origin and due to a destructive ulceration of the inflamed and stretched tubal wall.

Pathology.

209 Haemolysin Formation and the Suprarenal Glands

ACCORDING to D PERLA and J MARMORSTON GOTTESMAN (*Journ. Exper. Med.*, May, 1928, p 723), there is a great deal of evidence, from both morphological and physiological studies, that the suprarenal gland plays a significant part in the defensive mechanism of the body against intoxication. Studies during recent years have shown that the resistance of suprarenal-ectomized rats and rabbits to trauma and to various poisons and toxins is markedly diminished, particularly during the first few weeks following the operation. The authors have now tried to determine whether removal of the suprarenals in rats interferes with the production of antibodies. Their general technique was to subject a number of rats to suprarenal-ectomy, and subsequently to inject them and control rats with a single intraperitoneal dose of sheep red cells, the haemolysin titre of the serum was determined at intervals of five, eight, eleven, and fourteen days after injection. The results showed that the haemolysin production resulting from a single injection of 1 c.c. of a 10 per cent suspension of red cells was considerably lower in the experimental than in the control rats during the first five weeks following suprarenal-ectomy, the depression was most marked during the first week, and gradually wore off. But the surprising observation was made that if the dose of red cells was increased tenfold—that is, if 1 c.c. of undiluted red cells was given—the haemolysin production in the experimental rats was higher than in the control rats. After injection of the 10 per cent suspension a fortnight after suprarenal-ectomy the average titre of the normal rat five days later was 1 in 7,000, of the experimental rat 1 in 2,000, but after injection of the undiluted red cells the titre of the normal rat was only 1 in 2,000, whereas that of the experimental rat was 1 in 7,300. It would appear, therefore, that the effect of suprarenal-ectomy on rats is to diminish their power of producing haemolysin, and to increase by about tenfold the amount of antigen requisite to produce the optimal haemolysin titre.

210 A Possible Evolutionary Cycle in *Treponema pallidum*

C LEVADITI, Mlle R SCHOEN, and M V SANCHEZ-BAYARRI (*Ann. de l'Inst. Pasteur*, May, 1928, p 475) believe that the virus of syphilis undergoes a developmental cycle, of which the *Treponema pallidum* is only one of the stages. The evidence on which they base this belief is as follows. The inguinal and popliteal lymphatic glands of rabbits that have been inoculated into the scrotum prove virulent on injection into fresh animals, even though spirochaetes are very difficult or impossible to demonstrate microscopically in these glands. The authors examined thirty-three popliteal glands of syphilitic rabbits, and failed in every instance to detect spirochaetes by dark-ground illumination and by various staining methods. The virulence of eleven of these glands was tested; these were inoculated into twenty-four rabbits, in eighteen of which syphilis developed. Histologically it was found that implantation of a gland into the scrotum of a rabbit was followed by no marked change for seven weeks or so. The graft contained chiefly lymphoid tissue, a few giant cells appeared, but at no time were spirochaetes visible.

About the forty-fifth day the graft suddenly changed in appearance, the lymphoid tissue was replaced by fibroblasts, mononuclears, plasma cells, giant cells, and new vessels, and spirochaetes became visible in large numbers. The spirochaetes, however, were not all morphologically typical, inside the cells they appeared in involution forms, such as straight rods, club and dumb-bell forms, ring, pellet, and comma forms, and granules ranging from 0.4 μ to almost ultramicroscopic in size. Similar involution forms have been observed in syphilids of rabbits undergoing spontaneous retrogression, or retrogressing as the result of specific treatment. The authors suppose that the syphilitic virus is present in the lymphatic glands in the form of ultramicroscopic particles. When inoculated into a fresh animal these particles do not proliferate for some weeks, after this period they develop into the typical spirochaetes, and give rise to the usual histological changes of syphilis. These usually formed spirochaetes in their turn undergo involution, and pass once more into the ultramicroscopic phase. The authors suggest that this phase of the organism is more resistant to arsenic than the spirochaetal form, and that it is responsible for latent infections, and possibly for certain cases of paresis and general paralysis in which no spirochaetes can be demonstrated in the nervous system.

211 Specificity of the Tuberculin Reaction.

M MASTBAUM (*Zeit. f. Immunität u. exp. Therapie*, May 7th, 1928, p 147) brings forward evidence to invalidate the specificity of the tuberculin reaction. He finds that normal guinea pigs may be sensitized to tuberculin by treatment with a vaccine of *B. coli*. The vaccine is injected two or three times subcutaneously, only a certain proportion of the animals become sensitized, and the sensitivity wears off in a few weeks. A similar degree of sensitivity may be produced by injection of tuberculin mixed with pig serum. Of eight guinea pigs which received on two occasions a mixture of 0.3 c.c. of pig serum and 0.1 c.c. of old tuberculin, four subsequently reacted to the cutaneous tuberculin test. The author compares this artificial hypersensitivity to tuberculin with the allergy that occurs in tuberculous guinea pigs. The artificial hypersensitivity is not constant in its appearance and lasts only a short time, it is not very marked—that is to say, animals in this state will rarely react to less than 0.02 c.c. of old tuberculin. In true allergy the tuberculin hypersensitivity is constant in its appearance, it persists almost to the death of the animal, and it is marked by a reactivity to quite small doses of tuberculin—0.0003 c.c. These differences are, in the author's opinion, sufficient to prevent the two conditions from being regarded as identical. It is known that old tuberculin contains a large amount of non-specific material consisting of substances in the broth and protein degradation products. It is possible that these are responsible for the spurious tuberculin reactions that can be obtained by injection of *N. coli* and certain other substances. If this is so, it can still be maintained that the true tuberculin reaction is a specific phenomenon.

212 Action of Ethyl Alcohol on the Coagulability of the Blood.

G DI MACCO (*R. Morgagni*, May 20th, 1928, p 1049), as the result of intravenous injections into dogs of ethyl alcohol diluted with saline solution, came to the following conclusions: (1) Direct introduction of ethyl alcohol into the blood causes a decided increase of its coagulability, the increase being most marked about an hour after injection. (2) The coagulating power of the serum is increased in correspondence with the shortening of the coagulation time of the whole blood, on the other hand, the formation of fibrin and fibrinogen in the plasma appears to be diminished. (3) Alcohol *in vitro* accelerates and intensifies the coagulation of plasma prepared with magnesium sulphate. It is capable, even in the absence of serum, of causing the formation of fibrin when added to the plasma. (4) The changes are probably to be attributed to modification due to the presence in the plasma of alcohol, which activates the factors responsible for the transformation of fibrinogen into fibrin.

213 *B. paratyphosus A* Isolated from Epidemic Jaundice.

S COSTA, L BOYER, and MONTEL (*C. R. Soc. de Méd. Hyg. Jne 15th, 1928*, p 167) record a small epidemic of banku jaundice in troops returning from Syria in October, 1926. From four out of seven patients examined a bacillus was recovered identical with *B. paratyphosus A*, except for the fact that it produced hydrogen disulphide. This organism was agglutinated by a specific anti-*A* serum to a titre of over 1 in 5,000. The authors consider that this bacillus was causally related to the epidemic partly because all the cases occurred at about the same time, and partly because an apparently identical organism has been reported from other cases of epidemic jaundice in the East.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

214 Tobacco Smoking and Tabes

ACCORDING TO A WINKLER (*Med Welt*, August 4th, 1928, p 1160) although the majority of cases of tabes dorsalis are metasyphilitic, a very similar non-syphilitic condition occasionally occurs from the prolonged excessive use of tobacco, which he calls pseudo tabes nicotiana. It is always associated with visual symptoms. His patients were all over 50 years old, they were undernourished individuals with a history of excessive smoking for some twenty years. One patient aged 54 had absent knee jerks, pin point pupils which did not respond to light, attacks of giddiness, loss of memory, visual disturbances, and other symptoms. Romberg's sign was absent, and the Wassermann reaction negative. After four weeks' treatment with prolonged sulphur baths, warm mud baths, the use of sulphur waters, and complete abstinence from tobacco, the symptoms all subsided and the pupils and knee reflexes returned to normal. He emphasizes the importance of distinguishing this condition from the more usual one, since the prognosis is very good in the tobacco case if the patient gives up tobacco entirely, while in syphilitic tabes some improvement may result from treatment, but no complete cure is likely. Winkler considers it probable that tobacco merely disturbs the fibres in the posterior columns of the spinal cord, while syphilis destroys them.

215 The Heart in Whooping-cough

F. CHAJES ROSENBLUD (*Zeit f Kinderheilk*, July 7th, 1928, p 55) made a clinical and roentgenological examination of the heart in thirty-eight cases of whooping cough in children aged from 2 months to 7 years during the acute attack, and up to 15 months after its cessation. In thirty-one cases enlargement of the organ was noted, but in most cases it subsided a few months after the cough had ceased, the right auricle and right ventricle were the parts affected. The only clinical symptom indicating cardiac insufficiency was tachycardia, and there was no oedema or enlargement of the liver. Enlargement of the heart did not appear to depend on the age of the child, the severity of rachitic changes in the thorax, or the violence of the paroxysms, but the occurrence of febrile attacks appeared to be the most important factor. Of the 31 children who showed enlargement of the heart 43 per cent had an intercurrent disease, and of the 7 children whose heart showed no obvious change only one had an intercurrent illness, in the form of varicella, which ran an afebrile course.

216 Prevention of Measles

M. G. PETERMAN (*Amer Journ Dis Child*, July, 1928, p 123) reviews the progress made. First advocated by Nicolle and Conscif in 1918, the use of human convalescent measles serum and whole blood is now well established. A passive immunity of from six to ten weeks' duration is usually conferred by the intramuscular injection not later than the fourth day of the incubation period of human blood serum or plasma obtained within eight to ten days after the initial appearance of the rash, the dose is 5 c.c.m. for children aged 5, and 10 c.c.m. for older patients. From 15 to 30 c.c.m. of whole blood obtained and injected under the same conditions will be found as effective. The use of human convalescent blood or serum is, however, limited, adult donors are scarce, and children recovering from measles cannot well spare blood. Until antitoxins and detoxified toxins are made available for measles animal immune sera probably offer the most favorable solution of the problem of prevention. In January, 1926, Degkwitz reported favorable results in the prevention of measles with a specific serum obtained from sheep and monkeys, in the same month Tunneliff and Hoyle reported the production of an anti measles diplococcus serum in goats. Of a group of 34 patients inoculated in June, 1927, with this serum there was complete protection in 31 of the cases and a modification of the disease in the remaining 3.

217 Non diphtherial Membranous Laryngitis

C. RICCI (*Ospedale Maggiore*, June 30th, 1928, p 205), after alluding to the paper by Henneon (*Journal*, 1919, 1, p 604), who reported a series of cases of necrotic membranous streptococcal laryngitis, and to other writers on the subject, states that non diphtherial membranous laryngitis—two cases of which he records—may occur at any age of life, but is most frequent in childhood. Its severity varies. Coriat

distinguishes the following two forms. The first, which is most frequent in children, is characterized by special virulence of the organisms, it usually invades the whole respiratory system, and necessitates a guarded prognosis since about half the cases are fatal. The second form is mild and does not give rise to severe complications or much general disturbance, but remains confined to the larynx. Both Ricci's cases, which occurred in men aged 44 and 41 respectively, one of whom died and the other recovered, were due to the pneumococcus. In the first case, which was fatal, there was probably a pre-existing syphilitic lesion in the larynx, while in the second case, in which there was no fatal recovery ensued.

218 The Late Oculomotor Syndrome of Epidemic Encephalitis

T. HILUM (*Thèse de Paris*, 1928, No 46) bases his thesis on the study of seventy cases of chronic epidemic encephalitis in patients aged from 12 to 55 who showed various forms of oculomotor disturbances. The function of convergence was most frequently affected (54 cases), either alone or in association with paralysis of accommodation. Isolated oculomotor paralysis, which is a common symptom in the early stage, is exceptional in chronic encephalitis. Nystagmus is also less frequent than in the acute stage. As regards the intrinsic ocular muscles, while isolated paralysis of accommodation is exceptional in the late stage, and when present, is bilateral and ill marked, changes in the shape and reflex action of the pupils are frequent. The Argyll Robertson pupil is rare, but concentric affection of reaction to light and accommodation is common, and sluggish reaction of the pupils is also frequent. The palpebral symptoms are immobility, tremor, or exaggeration of the oculo palpebral reflex. Occasionally crises occur consisting in tonic or clonic deviations of the eyes in upward, downward, and lateral directions. The ocular symptoms occur in all varieties of chronic encephalitis, whatever their form may be, and their intensity bears no relation to that of the general symptoms. Their course is essentially progressive.

219 Arterio sclerosis of the Pulmonary Vessels

P. BENEDETTI and U. DE CASTRO (*Arch di Patol e Clin Med*, May-June, 1928, p 207) discuss the subject of arterio sclerosis affecting the pulmonary circulation, they record two personal cases and give details of 48 cases in medical literature. They epitomize the recent knowledge of this condition as regards its pathology, etiology, symptoms, diagnosis, prognosis, and treatment. Of the two personal cases one patient was a girl, aged 14, who suffered from primary arterio-pulmonary sclerosis with secondary tricuspid incompetence. The other was a man, aged 45, with arterio-sclerosis of the pulmonary artery and obliterating sclerosis of the small arteries secondary to chronic bronchitis, death occurred from failure of the right ventricle.

Surgery.

220 Surgical Treatment of the Pancreas

VON SCHMIEDEN and W. SEBENING (*Surg, Gynecol and Obstet*, June, 1928, p 735) discuss the surgery of the pancreas, based upon a study of 2,137 cases treated during the past eight years, with special consideration of acute pancreatic necrosis. The anatomico pathological picture shows simultaneous necrosis, inflammation, and haemorrhage, with great variations in type and degree, the necrosis being the dominating factor. Early operations for cholelithiasis are said to be justified prophylactically since pancreatic necrosis generally follows a neglected cholelithiasis, but the condition may arise without any sign of common duct complication. In treatment rapid drainage of the gall bladder will be sufficient if the large bile ducts are free from stones, but, if the condition of the patient permits, cholecystectomy with choledochostomy is the operation of choice. Since the pancreas is highly susceptible to operative trauma all possible damage must be guarded against, especially during operations on the gall bladder, stomach, and spleen. Mortality is high, being 51.2 per cent in 1,278 cases during the last eight years, and it is only in early operations that the best results can be obtained in acute pancreatic necrosis. The ideal aim in operation are to free the pancreas, protect against the spread of the toxic exudate, limit the process by draining away

the exudate, and prevent retention and downward in filtration. Any surgical intervention must be radical and prompt, cases without premonitory symptoms appear to be the most grave. The gravity of the prognosis is shown by the fact that 95 per cent of those not operated upon die.

221 Treatment of Infected Wounds

H. W. ORR (*Journ Bone and Joint Surg*, July, 1928, p. 605) recommends a form of treatment of compound fractures which makes no use of sutures, drainage tubes, or antiseptic dressings. The injured parts are first placed in correct position after which the wound is packed in every part with an aseptic non-absorbent vaseline mass, and a splint or cast is applied over a dry sterile dressing to keep the injured parts in a correct position during the entire period of healing. The vaseline pack facilitates drainage, and irrigation of the wound is not performed. The primary dressing is allowed to remain until healing of the wound is well established and primary consolidation of the fracture has occurred. This treatment has proved very satisfactory for recently contaminated but not actively infected bone and joint wounds, for such septic cases, treatment includes cleaning out the infected area, wide open drainage by a sterile pack, splinting in a correct position, and a careful avoidance of further irritative motion and the risk of infection following daily dressing procedures.

222. Rupture of a Varicocele by Indirect Violence.

A. LEHRNECHER (*Zentralbl f Chir*, June 30th, 1928, p. 1615) describes the case of a powerfully built labourer, aged 34, who, as the result of accidental compression of the abdomen by an overturned truck, had severe pain in the left inguinal region. A strangulated left inguinal hernia was suspected, and an attempt was made to reduce it without success. On admission to hospital the left half of the scrotum was found to be as large as a child's head and of a purplish colour. The swelling and discoloration extended above Poupart's ligament, suggesting an inguinal hernia with omental or vascular laceration, following the attempted reduction. An immediate operation was performed, the incision passing parallel to Poupart's ligament on the left side as far as the root of the scrotum, there was an extensive subcutaneous extravasation of blood. A haematoma as large as two fists distended the left spermatic cord, and there was a hydrocele of the left testis. Large blood clots were removed. Close to the epididymis there was more definite venous haemorrhage from a ruptured dilated vein in the pampiniform plexus, there was also rupture of a varicocele. The bleeding vessels were secured and Winkelmann's operation for varicocele was performed. No hernia was found, although the muscular development in the region of the inguinal canal was poor. The pillars of the ring were sutured, and the wound was drained by a tube passed through the lowest part of the scrotum and by strips of iodoform gauze. Healing was uneventful. The author believes that rupture of a varicocele is a very rare accident, he has been unable to find any reference to it in the literature. In this case it was evident that the accident caused a great increase of intra-abdominal pressure, which was transmitted to the pampiniform plexus and the varicocele, thus producing rupture of the veins.

223. Traumatic Shock

E. COWELL (*Journ Roy Army Med Corps*, August, 1928, p. 81) reviews the various theories as to the pathology of and factors in producing shock, and relates his own experiences during the war in this matter. He defines shock as the clinical condition which follows an injury, producing depressed vitality, and being associated with lowered blood pressure, deficient circulating fluid, diminished intracellular oxygenation, and reduction in the body temperature. Such a condition results from one or more of the following factors, acting either singly or in combination—pain, haemorrhage, cold, toxæmia of bacterial or other origin, and anaphylaxis. Sustaining factors are the low blood pressure and decreasing blood volume. The results produced are a diminished circulating fluid, deficient intracellular oxygenation, and devitalization of important organs, such as the heart, kidneys, and brain. Secondary traumatic shock is the common type, and only becomes established slowly. Prophylaxis is successful in many cases, and in the operating theatre shock may be avoided by warmth, a suitable anaesthetic (local, spinal, or gas and oxygen in a bad case), haemostasis, and gentleness in handling the tissues. Chloroform, and to a lesser extent ether are powerful toxic agents, and, if employed after the trauma, a chemical toxæmia may be added to the shock causation complex with serious results. Starving the patient and withholding fluids too long beforehand tends to anhydremia and is to be avoided. A small dose of morphine is useful in allaying undue mental pre-operative apprehension. If shock develops and a blood pressure of 80 mm Hg does

not respond in half an hour to such simple methods as the application of warmth, mental rest, and the relief of pain, other measures must be adopted. The deficient circulation may be restored by giving fluids by the mouth or rectum, or administering 10 per cent glucose saline solution intravenously (1,000 c.c. in two hours). Intracellular oxygenation may be increased by the hypodermic administration of 5 units of insulin at the beginning and end of the glucose injection. Even after a severe haemorrhage this will tide the patient over the crisis, and transfusion of whole blood may be performed subsequently if necessary. The question of operating in shock must be decided in each case, and under suitable anaesthesia surgery may be the only means of removing the cause of a toxæmia and, thereby, saving the patient's life.

Therapeutics

224. Treatment of Pulmonary Tuberculosis by Inhalation of Calcium Salts and Carbon

WILLIAM P. NOLAN (*Med Journ and Record*, July 4th, 1928, p. 6) describes a method of treatment of pulmonary tuberculosis by use of an inhaling box containing a mixture of carbon powder and calcium salts, which is driven towards the mouth piece by an electric fan. According to Nolan the inhalation of carbon particles gives rise to a maximum proliferation of phagocytic capillary endothelial cells, and subsequent blocking of lymph channels connected with diseased areas, this stops the absorption of toxic products and prepares the way for final calcification, which is hastened by the direct supply of lime salts to the pulmonary alveoli. Healthy areas of the lung do not appear to share in the process of calcification. This form of treatment was first tried as the result of the observation of exceptionally low mortality figures for pulmonary tuberculosis in certain coal mining areas and cities with particularly smoke-laden atmospheres. Nolan insists that the treatment is not a panacea and should be given only as an adjunct to the usual general hygienic measures, moreover, good results are not to be expected from it in advanced cases. It is claimed that morphological changes have been found to occur in tubercle bacilli obtained from subjects under treatment, the characteristic staining reactions and the virulence towards experimental animals disappearing. In Nolan's series 114 cases were treated, all were of moderate severity, as shown by physical and x-ray examination and the presence of tubercle bacilli in the sputum. In no case after the commencement of treatment did there appear haemoptysis, laryngitis, or pleurisy with effusion. All the patients were discharged as clinically inactive, there being no haemoptysis, no persistent rales and no x-ray evidence of tuberculous lesions in the upper half of the chest, no pleurisy with effusion, no tubercle bacilli in the sputum, no pyrexia or exorise, and a maintained increase in weight. Treatment was not attempted in cases of far advanced or rapidly progressing disease, or where there was definite evidence of ulcerative laryngitis.

225. Anaphylactic Asthma Relieved by Bleeding

P. VALLÉRY RADOT, P. BLAMOUTIER, and L. ROUQUÈS (*Bull et Mém Soc Méd des Hôp de Paris*, July 19th, 1928, p. 1191) describe three cases of asthma due to sensitization in which bleeding out short the attacks, and in some instances prevented their recurrence despite exposure to the provocative protein. This method of treatment was suggested by the occurrence of traumatic haemorrhage during an asthmatic attack in a baker who was sensitive to flour, immediate relief resulting. Both in this case and in another similar one specific desensitization had produced no effect, but with drawal of blood in amounts varying between 75 and 300 c.c. was followed by abbreviation of the attack and immunity for days, weeks, or even months afterwards. In the third case the attacks were occasionally apparently unprovoked, but were sometimes due to the inhalation of mustard, even the withdrawal of 20 c.c. of blood gave some relief within a minute or two, while the removal of another 100 c.c. on a total of fifteen minutes an attack which ordinarily lasted three quarters of an hour, despite the administration of ephedrine and ephedrine. None of the cases showed any signs of cardiac or renal insufficiency. The possibility that these results were produced by suggestion is considered by the authors, their view that suggestion could not account for the disappearance of symptoms for four months despite exposure to the particular sensitizing agent was confirmed by various control experiments performed by them. Results from this method were not consistently good, two patients sensitive to horse hair and serum failed to respond to bleeding, nor was any relief obtained in eight cases of severe asthma unrelated to any protein sensitization.

226 The Treatment of Impetigo Contagiosa Neonatorum

H G HOLDLER (*Amer Journ Obstet and Gynecol*, June, 1928, p 857) states that impetigo contagiosa of the newborn infant presents a serious problem in maternity hospitals, its ease of transmission and, at times, its high mortality causing it to be much dreaded. The treatment in 115 cases is reported, one or other of the following methods being employed: 3 per cent tincture of iodine in 25.2 per cent of the cases, 10 per cent ammoniated mercury ointment in 18.2 per cent, 1 per cent aqueous solution of mercurochrome in 5.2 per cent, and 2 per cent aqueous solution of gentian violet in 51.3 per cent. In each case the vesicle was surrounded by the agent used, and ruptured under aseptic precautions. The exfoliated epidermis was then removed and the medicament was applied directly. The order of efficiency of these substances was found to be: (1) gentian violet, (2) mercurochrome, (3) iodine, and (4) ammoniated mercury ointment. Mercurochrome was satisfactory, but did not produce such rapid delimitation and eradication of the infection as did gentian violet. Iodine was also effective, but was frequently too irritating. Ammoniated mercury ointment was found to be detrimental to rapid healing, it was not only ineffective, but prolonged infection and favoured complications. Gentian violet was tried, as the cause of infantile impetigo is supposed to be a strain of *Staphylococcus aureus*, and Churchill has shown that this dye has a selective bacteriostatic action on Gram positive organisms, penetrating other organisms and living cells without deleterious effect. Its use was strikingly beneficial, definite improvement occurring in twelve hours and entire healing in a week. More than one application of the gentian violet is seldom necessary, there being an immediate arrest of extension. Desiccation is rapid, and the thin crust formed permits of epithelialization under the surface, with normal desquamation of the crust in about forty-eight hours. There was a notable absence of recurrences in the cases so treated, after discharge only four patients returned for further treatment, and these showed merely minor recurrences.

Anaesthetics

227 Spinal Anaesthesia in Abdominal Operations

L F SISE (*New England Journ. Med.*, July 12th, 1928, p 59) prefers spinal anaesthesia in abdominal operations, since it combines complete relaxation with freedom from the injurious after effects, predisposition to surgical shock and lung complications often following ether anaesthesia. By its use patients can be dealt with who would be inoperable under any other method, or likely to succumb under a general anaesthetic. The method is safe, provided that care is taken in selection, and the pulse, blood pressure, respiration, and colour are carefully watched throughout, adequate measures being adopted if urgent symptoms appear. During operation better relaxation is obtained than by any other form of anaesthesia, the patient's breathing is quiet and shallow, the intestines are contracted, and the post-operative condition is distinctly better than with ether, comparing favourably with that following ethylene and regional anaesthesia. The preliminary administration of ephedrine maintains the blood pressure satisfactorily, and solutions of specific gravity less than that of the spinal fluid may be used, the heavier solution being preferable for most upper abdominal operations and the lighter for the lower ones, especially those requiring the Trendelenburg position. Sise describes the technique of injection in detail with suggestions for the treatment of complications, he points out the danger of giving too much ephedrine in the presence of a weak heart, regarding salt solution or epinephrine as safe if more than the preliminary dose of ephedrine is required.

228. Carbon Dioxide Anaesthesia.

E FISCHER (*Zentralbl f Gynäk*, August 11th, 1928, p 2010) has used carbon dioxide as an adjuvant anaesthetic in 300 cases of abdominal or vaginal operation with good results, both as regards anaesthesia and after effects. He sums these as follows: The most important action of this gas is on the respiration, dyspnoea and asphyxia occurring during the anaesthesia are due to lack of oxygen and not to excess of the anaesthetic. Inhalation of carbon dioxide raises its concentration in the blood, and, consequently, the respiratory centre is stimulated, respiration becomes deeper and more frequent, resulting in an increased intake of oxygen and output of superfluous anaesthetic. The circulation is improved, the blood pressure, usually lowered during anaesthesia is raised above the normal and then falls again. The good effect of the gas on the circulation guards against post-operation shock, and possibly thrombosis. In lung complications carbon dioxide is valuable through the enforced deep breathing and improved circulation which is already estab-

lished pneumonia and bronchitis help to expel secretion. Patients recover consciousness quickly and with less sickness and vomiting than usual. Carbon dioxide is also useful after an operation to stimulate patients who are semi-comatose, the effect is only temporary and may have to be repeated frequently. The apparatus Fischer uses consists of a cylinder and valve connected with a flask from which a tube leads to a gum elastic connexion, to this a thin rubber catheter is attached. The catheter is inserted into one nostril, and the patient obtains air through the other nostril and the mouth after three to four breaths the breathing grows deeper and quicker, the face becomes a rosy red, and the pulse is found to be fuller, stronger, and quicker. Carbon dioxide is pushed during induction if the respiration is shallow, and in asphyxia. If the breathing should stop, artificial respiration must be employed to cause intake of carbon dioxide. Towards the end of an operation carbon dioxide alone is given, its administration is repeated the same evening and the next morning and more often if necessary. The method, in Fischer's opinion, undoubtedly lessens the risks of chloroform and other anaesthesia, and it has the additional advantage of cheapness.

229

Stovaline Analgesia

W BARRAS (*Brit Journ Anaesth*, July, 1928, p 1) advocates the induction of spinal analgesia by the injection of stovaline in selected cases, the indications for its use being patients for whom inhalation anaesthesia is contraindicated and operations requiring complete muscular relaxation. The soluble salt stovaline hydrochloride is precipitated by alkalis, small traces of which lessen its analgesic properties. It is stable and capable of sterilization at 115° C. The maximum dose is 0.1 gram, and several solutions are in common use. Barras deprecates any elaborate preparation of the patient, but advises a little stimulant beforehand with a preliminary injection of morphine sulphate 1/6 grain and hyoscine 1/100 grain. Under strict asepsis injection is made through a lumbar space after a definite flow of cerebro-spinal fluid has been obtained. Numbness of the feet and legs and sensations of heat and cold are felt immediately after the injection, and impairment of pain sensation generally commences from two to three minutes later, the maximum effect of muscular paralysis is attained in from ten to fifteen minutes, and persists for from fifty to ninety minutes. Vomiting, which occasionally occurs during the analgesia, may be controlled by oxygen inhalation, while a fall in blood pressure is best restored by ephedrine hypodermically. Barras advocates ether inhalation as a restorative having been impressed by the effect of light ether anaesthesia when used to supplement the stovaline. Faintness and collapse due to extreme fall in blood pressure may be treated by adopting the Trendelenburg position, subcutaneous injections of adrenaline with massage of the site of injection to promote absorption may be useful. The author adds that the responsibility for the injection and for the general condition of the patient should be in the hands of a competent anaesthetist throughout.

Obstetrics and Gynaecology.

230.

A Round Ligament Reflex.

F I IMANITOFF (*Brussels Medical*, August 5th, 1928, p 1310) maintains that the round ligament possesses a reflex which can be utilized in the treatment of uterine retroversion. These ligaments arising immediately in front of and a little below the tubes, and being inserted among the connective tissue and muscular fibres of the labia majora, constitute a direct connexion between the uterus and the labia. Histologically they show the same structure as the uterine walls, and are thus the direct organic continuation of the uterus. In addition to smooth muscle fibres, the ligament, in its passage through the inguinal canal, receives striated fibres from the transversalis and internal oblique muscles, these forming the cremaster muscle. The axial part of the ligament contains its vascular supply, and these vessels are accompanied by nerves from the uterus. De Vicentis has shown that there is a relation between the abdominal organs and the cutaneous areas with which they are associated by sympathetic reflexes, and the present author holds that such a reflex exists in the round ligament entirely comparable in its sympathetic origin with other reflexes. The author remarks that the cremasteric reflex, present in the female though less marked than in the male, must not be confused with the round ligament reflex, though the two are complementary. These reflexes can be produced by stimulating, preferably with a high frequency current, the circumference of the hairy triangle of the mons and the inner surfaces of the thighs. This causes a contraction of the smooth fibres of the ligaments, and since these are in direct continuation with the uterine ones, a tonic contraction of the uterus ensues.

which straightens and draws it forward. The technique of the method is described. The only contraindications to its use are said to be retroversions due to tumours or adhesions. Usually twelve to fifteen applications suffice to restore the uterus to its normal position. Lianistoff reports 36 cases of retroversion due to abortion or post partum infection, and one juvenile case of lateral deviation, they were successfully treated in the manner described. In only three cases was there a recurrence of the trouble, but a second series of six applications definitely replaced the uterus normally.

231 Wounds of the Vagina from Coitus.

ACCORDING to A. BELLEI (*Ann di Ostet e Ginecol*, June 30th, 1928, p. 632) lesions of the vagina during coitus are less rare than the paucity of recorded cases would suggest, they are not less common among multiparae than nulliparae, but have been infrequently reported after the menopause. They are more common among the lower social classes, but only two cases have been reported as occurring in prostitutes as a rule, coitus has been in the normal position, and the lesion is often caused by the violence of an extra nuptial but voluntarily accepted congress. As a rule, vaginal wounds in mature persons after unforced coitus are not associated with disproportion, the most important causative factor is excessive vigour, especially on the part of the female. Etiological factors favouring injury to the vagina are (1) genital hypospasia, (2) pregnancy and the puerperal state, (3) previous vaginal operations, (4) abnormal direction of the vulvo vaginal canal, (5) presence of large faecal masses in the rectum. Diagnosis is generally easy, but reluctance of the patient to explain the true cause of the pain and haemorrhage may sometimes lead before examination to suspicion of incomplete abortion. The mortality, if published cases only were considered, would appear to be as high as about 7 per cent. Bellei describes ten cases, one of which—that of a forced coitus in a woman aged 48—proved fatal from septicaemia. In his series the relation of the accident to the last menstruation is recorded—about fifteen days had elapsed between the two in all cases. It is suggested that lesions at this time are favoured by increased sexual desire in the female during the days following ovulation.

232 Delivery of the Anencephalic Foetus.

H. NAUJOKS (*Zentralbl f Gynäk*, July 21st, 1928, p. 1818) quotes the report of Eierland, who has described a series of thirty cases of delivery of anencephalic monsters. The diagnosis was made after delivery in nineteen, at the end of the second stage of labour in eight, and during the second stage in three. Naujoks describes three cases in which diagnosis of the presentation was not made until shortly before birth, breech presentation having been expected. He points out that early recognition of the anomaly is frequently made more difficult by a coexisting hydramnion, which occurred in one half of Eierland's cases of anencephaly, and in an even larger proportion in cases reported by other authors. Radiological examination during pregnancy has occasionally led to detection of an anencephalic foetus, and Naujoks records a case in which the use of x-rays spared the patient considerable suffering. A 5 para, aged 34, was admitted to hospital five weeks before term for severe abdominal pain and great distension of the belly, combined with symptoms suggesting pregnancy toxæmia. The foetal parts and position could not be identified by intrapelvic or abdominal palpation. Radiography showed an anencephalic foetus, and labour was forthwith induced.

Pathology.

233. The Action of Lecithin on the Blood

A. GRÖNBERG and Å. LUNDBERG (*Acta Med Scand*, August 13th, 1928, p. 99) state that, following Magat's work proving that in rabbits injections of lecithin caused an erythrocytic increase, a 10 per cent emulsion of lecithin in glycerin has been used in the treatment of grave anaemias. The authors have made a series of experiments, both *in vitro* and *in vivo*, to ascertain whether lecithin increased the resistance of the red cells to hypotonic sodium chloride solutions, and, if so, whether similar results were produced in men and animals, they also tried to elucidate the action of lecithin in anaemias. The brownish yellow lecithin emulsion was administered intravenously in 5 gram doses and intramuscularly in doses of 15 grams in the latter injections 1 per cent of novocain was added. The *in vitro* tests were made on blood diluted with physiological salt solution and with distilled water, and on blood to which haemolysing agents such as saponin and bothriocéphalus extract had been added. The other experiments were made on rabbits and on nine patients suffering from various diseases. In two

of these cases a pronounced anaemia existed, the erythrocyte count being normal in the others, the emulsion was administered intramuscularly in one case and intravenously in the remainder. The results showed that lecithin does increase the resistance of the red cells to hypotonic solutions and haemolysing agents, but that to produce this action the lecithin must be emulsified in oil or glycerin and the emulsion carefully shaken before use. The erythrocytes were increased in the anaemic patients and in those with a normal cell count. Two hypotheses are given as to the action of lecithin: (1) that it is a purely physico-chemical phenomenon, and (2) that it is a biological reaction of one or more parts of the organism. Pending further experiments, the authors incline to the former view.

234 Efficacy of Antidiphtherial Serums.

E. TECHOUEYRES (*Presse Méd*, July 21st, 1928, p. 918) mentions the continued appearance of serious forms of diphtheria which do not respond, as might be expected, to treatment with serum. The remedy has sometimes been suspected, and to overcome the difficulty, larger and more concentrated doses have been given. However, Grenet and Delnne found that children treated with a serum rich in antitoxin gave a mortality of 23.5 per cent, whereas during the same period and in similarly severe cases serum of half the strength gave a mortality of only 13.43 per cent. Thus there seems to be no relation between the antitoxic strength of a serum and its curative effect. Techoueyres quotes Nicolle's former view, which was that two groups of factors were concerned, the one relating to immunity (conglins), the other to sensitivity (lysins). Seeing that clinical results do not agree with the theory, he proposes a hypothesis depending upon perpetual change or continuous evolution. He remarks that the quality of producing immunity attributed to this act of coagulation may perhaps be a wrong interpretation, substituting for a real and continuous progress a fixed and precisely defined state. This idea is illustrated by a table showing the effect of alcohol on several types of bacteria in which the lethal period increases with the stronger solutions, the purer alcohol coagulates the albumin and prevents penetration into the interior. He concludes by asking whether the increase in the strength of antitoxin solution does not act in a similar manner.

235 The Relation between *B. pseudotuberculosis rodentium* and *B. pestis*.

S. J. ZLATOGOROFF and Mme B. MOCHILEVSKAIA (*O R Soc de Biologie*, July 13th, 1928, p. 505), endeavouring to find some method for distinguishing *B. pseudotuberculosis rodentium* from *B. pestis*, have come to the conclusion that these two organisms are even more closely related to each other than is generally supposed. Two cultures of the pseudo-tuberculosis organism were cultivated in broth containing only a trace of peptone for about four weeks, they were then plated out on agar. Two sorts of colony were noticed—a smooth and a rough, intermediate forms between these two main types were also observed. The two type colonies were obtained in pure culture. It was then found that the smooth type was highly virulent for the guinea pig, and that in its cultural and biochemical reactions it was practically identical with *B. pestis*. The rough form, on the other hand, was only slightly virulent or actually non-virulent for the guinea pig, and in its cultural and biochemical reactions it preserved the properties of the parent strain. A difference in receptors was found between the rough and the smooth form. The authors conclude that *B. pseudotuberculosis rodentium* can produce a smooth variant which is for all practical purposes indistinguishable from *B. pestis*. They add that this observation establishes a whole series of new problems in the detection of endemic foci of plague.

236. Granulomatosis Siderotica of the Spleen

O. Z. ATTILIO (*Arch di Patol e Clin Med*, May-June 1928, p. 122) reports a case of this condition which was described by Gamma in 1923. He examines critically the French and German literature on the subject and expresses the belief that the "nodules tabac" described by Gamma are not specific for this form of splenomegaly, but are common in other types of splenic enlargement. He does not think that it is definitely mycotic in origin, although mycosis cannot be excluded as a secondary infection. The author's patient presented some of the symptoms of Banti's disease in the second stage, but there was no urthraur or relative lymphocytosis, attacks of fever occurred at times, and there was some enlargement of the inguinal glands, probably an intercurrent affection. When the spleen was removed an intercurrent affection. When the spleen was removed Gamma nodules were found, histologically "necrosiderotic". The liver was normal except for slight fattiness. After splenectomy the patient improved. Numerous drawings of the histological appearances are reproduced.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

237 Acute Yellow Atrophy following Cinchophen Administration

D. C. SUTTON (*Journ Amer Med Assoc*, August 4th, 1928, p 310) reports a case of cinchophen poisoning, the patient, a woman aged 27, having taken a total of more than seventy tablets as a remedy for joint pains. The first symptoms were a yellow discoloration of the skin, followed by a very irritable eruption over the face, arms, and body. Some days later there began attacks of a feeling of constriction of the chest, associated with humming sensations there and in the throat and face. Two face lips, and tongue became greatly swollen, the pulse rate increased, and there was vomiting, after about an hour the symptoms subsided. These attacks ceased after about a week. Two months later ascites increased rapidly, and the patient died after an attempt to relieve this condition by means of a Lanza-Narath operation. The liver contained sharply circumscribed yellow areas and a surrounding dark red portion, the areas occupying more than half the total cut surface. Many liver cells showed extreme fatty degeneration and actual necrosis, the bile ducts proved more resistant to the toxic process. The convoluted tubules of the kidney were dilated and filled with a form of granular material, the lining epithelium being swollen, as were the glomeruli. Sutton suggests that the benzoin ring in this preparation causes the jaundice, and that under some conditions the oxidation in the liver of the quinoline nucleus may produce highly toxic nitrogenous compounds. He refers to reports of similar cases in the literature (see *Journal*, 1926, Vol II, pp 37, 93, 136, 273-299). While admitting that this drug is most efficient in acute gout, he gives a warning that it should be used only during attacks of pain and be immediately withdrawn should urticaria, gastric distress, or jaundice appear.

238 Typhoid Fever in Peking

S. H. ZHANG (*Nat Med Journ of China*, April, 1928, p 105) records his observations on 256 typhoid fever patients admitted to the Peking Union Medical College Hospital between July, 1921, and the end of 1927, of these, 203 were males and 53 females. During the same period there were 48 cases of paratyphoid A and 17 of paratyphoid B. Over half the cases occurred in patients between 16 and 25 years of age. The youngest patient was aged 1½ and the oldest 48 years. Most of the patients were of the student, soldier, and labouring classes. The highest incidence came in the months immediately after the hottest season, in 29 cases there were relapses, the average interval between the end of the initial attack and relapse being seven to eight days. Intestinal haemorrhage occurred in 20 per cent, perforation in 3 per cent, and parotitis in 3 per cent. The annual mortality varied from 5.8 to 26.3 per cent, the average being 15.6 per cent.

239 Venous Blood Pressure in Hyperplasia

C. ALEXANDRESCO-DESCA, D. JONESCO, and V. BALACEANU (*Paris Méd*, August 11th, 1928, p 133) review the advances made in recent years in the study of peripheral venous blood pressure. Using the technique of vein puncture elaborated by Villaret, they have investigated the venous pressure in thirty cases of chronic hyperplasia, the measurements being made in each case under exactly similar conditions. They found increased pressure in the veins in these patients suffering from early cardiac insufficiency or definite failure of the right heart, and also in cases of advanced renal disease. The pressure in such patients varied between 17 and 60 cm of water as compared with the normal 12 cm. Intrapulmonary hypertension, whether arising from bronchitis, emphysema, fibrosis, or sclerosis of the pulmonary artery, was also found to raise the intravenous pressure. Reduction of the venous pressure to 7 or 10 cm of water was observed in cases of hypertension accompanied by arterio-sclerosis or any other lesion involving the smaller blood vessels and capillaries. In a third group, in which high blood pressure was not complicated by cardiac, pulmonary, or vascular lesions, a normal venous blood pressure was the rule. From these results it is inferred that the determination of venous pressure is of diagnostic value because it is an index of the functional integrity of the right heart. Further, if it is reduced *pari passim* with the arterial pressure as a result of treatment, the outlook is more favourable, since the heart has responded to therapeutic measures. Venous pressure

measurements are therefore of use in prognosis, but they are also valuable in therapeutics, thus readings taken from time to time may help to determine the activity of particular remedies in cases of hypertension, chronic uraemia, and high blood pressure due to disease of the lung or its blood vessels.

240 Skin Sensitivity in Scarlet Fever

JEAN V. COOK (*Amer Journ Dis Child*, May, 1928, p 762) finds that skin sensitivity to scarlatinal streptococcus filtrate toxin, which is present in only a small number of infants at birth, increases slowly during the first six months and more rapidly during the last half of the first year. It remains high from the second to the sixth year and falls during the school age. The relative absence of skin sensitivity during early infancy and the rather gradual development of this property later might have several possible explanations—as, for example, the assumption of an inherited antitoxic immunity from the mother in early life which disappears later. The possibility that the skin sensitivity is dependent on an acquired hypersensitivity to streptococcus protein must also be considered. Haemolytic streptococcus infections of the upper respiratory tract are extremely prevalent in infancy, and the opportunity for such a sensitization in early life is therefore present. The decrease in skin sensitivity in later childhood is apparently associated with the presence of specific neutralizing antibody (antitoxin) in the blood. This immunity is probably acquired as a result of later streptococcal infection.

241 Lymphogranulomatosis Maligna.

A. DALLA VOLTA (*Arch di Patol e Clin Med*, May-June, 1928, p 167) publishes two cases of this condition especially affecting the spleen. The blood was marked by a diminution of platelets and granulocytes, while the lymphocytes were almost normal. Examination of the myeloid tissue showed that these blood changes were myelopathic in origin, and due to a partial hypoplasia of the bone marrow, which in its turn was attributable to a toxic process of splenic origin. The author has found x-ray therapy useful in these cases, applied especially to the spleen.

Surgery.

242 Biliary Intestinal Anastomosis for Obstructive Jaundice

E. S. JUDD and B. R. PARKER (*Archives of Surgery*, July, 1928, p 1) report the results of operation in 137 consecutive cases in which anastomosis of the biliary and gastro-intestinal tract was performed. Each patient with jaundice was treated before operation with a diet rich in carbohydrates and was given fluids and calcium chloride injections. Many of the malignant cases were hopeless and required heroic measures for their relief. In the 137 cases there were 9 of contraction of the stoma. Return of symptoms occurred from one to six months after operation, and reconstruction of the stoma over a rubber tube was effected in each case. Five patients have survived from two to four years after operation and ten have been completely relieved of their former trouble, three cases are reported as much improved. There were 62 cases of stenosis of the bile ducts following operation. It was noted that the trouble appeared immediately after the primary operation in certain cases, and was probably due to a continuation of the inflammation in the bile ducts, which finally resulted in obliteration. The authors add that many cases attributed to trauma are due to obliterative cholangitis. Various types of operation were performed, and 17 patients were completely freed from their symptoms. A review of the general results was not encouraging, but the end results were satisfactory in cases in which there was a reasonable chance of improvement or cure.

243 Statistics of Prostatectomy

P. CIELESKY (*La Ved Ibera*, August 4th, 1928, p 108) has performed prostatectomy on 226 patients. Of 90 patients treated during the period 1910 to 1917, 72 recovered and 18 died, a mortality of 20 per cent, while of 136 treated between 1920 and 1928, 126 recovered and 10 died, a mortality of 7 per cent. The better recovery rate in recent years is attributed to improved technique, especially packing the cavity, performance of the operation in two stages, and a careful

selection of cases While 142 cases occurred in hospital practice with a mortality of 14 per cent, there were 84 in private practice, with a mortality of 7 per cent. The causes of death were haemorrhage 8 cases, broncho pneumonia 6, naemia 5, generalized infection 4, cardiac failure 2, shock 2, and pyelonephritis 1. General anaesthesia with ether and chloroform was employed in 167 cases, spinal anaesthesia in 58, and general anaesthesia with ethyl chloride in 1. 31 patients developed epididymitis, which in only one case terminated in suppuration, and 21 had pyelonephritis, which was severe in only two instances, one patient dying. In 2 cases post-operative stricture developed in the deepest part of the membranous urethra, in 3 cases the operation was followed by prostatitis, which in 2 was mild, and in 1 ended in an abscess which had to be opened through the perineum. Perineitis occurred in 12 cases, in 9 being of a mild character, and in 3 ending in an abscess which was evacuated into the urethra in 2 cases and externally in 1. In 9 cases cicatrization was slow, but no permanent fistula resulted. Four patients had a mild form of phlebitis of the lower limbs accompanied by a slight rise of temperature, three patients developed secondary vesical calculi a few months after the operation owing to persistence of infection in the bladder. Like most urologists Cifuentes is in favour of the hypogastric operation performed in two stages.

244. Simple Facial Erysipelas with Streptococci in the Blood and Urine.

H. HOFFMANN (*Med Klin*, July 27th, 1928, p. 1164) states that in uncomplicated erysipelas the prognosis is good in the majority of cases when the blood is free from streptococci, but when these are present in the blood stream, the probability of a generalized septicaemia renders the prognosis much graver. Hoffmann's patient was a boy aged 11 who had suffered from lupus vulgaris of the nose and nose since he was 4. He had also lupus on the left arm and on both great toes, and the nasal mucosa had been invaded. The patient had been under treatment since January, 1927, with rays, pyrogallol, and tuberculin had been tried. The pulmonary physical signs were suspicious, but skiagrams showed nothing definite. The heart appeared to be normal. The Pirquet reaction was definitely positive. One day the boy's temperature rose suddenly to 104.2° F. with painful erythema of the nose and left cheek. Erysipelas of the nose spread rapidly over the whole face and invaded portions of the scalp; there was severe headache and slight general malaise. On the seventh day the temperature rose to 106.3° F., and a pure culture of a haemolytic streptococcus was obtained from both blood and urine. There was a leucocytosis of 13,700 and the lymphocyte count was 14 per cent. Albuminuria was absent, and the spleen was not palpable. Two days later the erysipelatous swelling disappeared, and the patient was discharged in good general health four weeks after his admission. Hoffmann comments on the great rarity of streptococcal invasion of the blood and kidneys in uncomplicated cases of erysipelas, and also notes the remarkable fact that a haemolytic streptococcus in the urine failed to produce albuminuria, although this sign is found in about half the cases. Actual acute nephritis occurs only in 2 to 3 per cent of cases of erysipelas. According to one German writer the death rate from septic facial erysipelas amounted to 68.75 per cent, another gives the death rate of facial erysipelas in children as 15 to 20 per cent.

245. Primary Carcinoma of the Ureter

L. P. PLAYER (*Urol and Cutan Rev*, July, 1928, p. 438), who has collected thirty nine cases, including a personal one, states that this tumour occurs with equal frequency in both sexes. The ages of the patients range from 30 to 89, but the sixth decade is most affected. The three main symptoms are pain, haemorrhage, and tumour. The pain may be variable in character, it often starts in the lumbar region, occurs in crises, and sometimes there may be renal colic with pain radiating towards the bladder. Haematuria is the most constant symptom. A tumour may be detected by bimanual palpation under the bladder near either ureteral opening. When a mass can be felt in the lumbar region as a result of ureteral tumour, the neoplasm has usually advanced so far as to produce obstructive symptoms resulting in a hydronephrosis, haematonephrosis, or pyonephrosis. Anaemia, which is a less frequent symptom, may become bilateral, due to sympathetic involvement of the other ureter, carcinomatous involvement of the muscular coat of a patent ureter may also cause total obstruction by blocking the peristaltic waves. Treatment consists in early removal. Player's patient was a woman aged 65, with a history of haematuria of two years' duration. A diagnosis of neoplasm of the left ureter with hydronephrosis was made and confirmed at the operation, when nephrectomy and ureterectomy (upper half) were performed. The tumour proved to be a papillary epithelioma. Benign

metastatic papillomatous growths in the bladder were treated by fulguration. The patient remained in good health for two years after the operation and then complained of pain in the left side, she passed increasing amounts of blood, became cachectic, and died.

246. Indications for Appendicostomy

G. COTTE and P. BRITRAND (*Lyon Chir*, May-June, 1928, p. 305) describe the indications for appendicostomy. The operation they have employed has been as a caecal fistula rather than a true appendicostomy, the caecum and base of the appendix being sutured to the parietal peritoneum. A urethral sound has been used to keep the opening patent, and the fistula has always closed spontaneously when this has been removed. Appendicostomy has been employed with advantage in cases of paralytic ileus following peritonitis, and in surgical affections of the large intestine, such as malignant growths, with or without obstruction, acute chronic dysenteric ulceration, and volvulus of the sigmoid colon. It has also proved of value for introducing saline solution into the bowel after serious abdominal operations. Appendicostomy has been used with success in cases of severe gastric haemorrhage, both as a means of administering fluid and of evacuating the blood from the bowel. The operation is said to be valuable in all those conditions, and has in no single instance been followed by any unsatisfactory results. While it cannot be said that it has actually saved the life of any patient, it has certainly proved distinctly beneficial in the conditions described.

Therapeutics.

247. Remedial Measures for Cardiac Neurosis.

W. SCHOLZ (*Wien Klin Woch*, July 5th, 1928, p. 951) emphasizes the importance of regarding the vague condition of cardiac neurosis as part of a general neurasthenic state which leads the patient to take undue interest in heart sensations which are of little or no pathological significance. After determining by careful examination that there is no evidence of commencing heart disease, and winning the confidence of the patient, Scholz advises residence at or above the sea coast and the encouragement of physical activity. In severe cases such as those of "heart cramp" small doses of cocaine may be effective, or a mixture of the tinctures of aconite and valerian, rubbing the chest with alcohol, ether, or vinegar is also commended. In less acute cases the most useful remedies are the bromides, valerian, iron, arsenic, and quinine, arsenic in the form of injections has a suggestion value, and involves a closer medical supervision which may be advantageous. Cocaine and morphine preparations are contraindicated. Lukewarm baths each morning have been found useful, and to them may be added salt, thyme, and pine extract. Massage, air baths, faradic stimulation, and "four cell" baths may also be tried. Holotherapy under careful medical control is sometimes beneficial. Symptomatic treatment of such conditions as sleeplessness and loss of appetite should not be omitted. For relief of the unpleasant sensations caused by extra systoles becoming perceptible, the administration of quinine three times a day has been found useful.

248. Treatment of Alkalosis in Peptic Ulcer

W. E. GATEWOOD, O. H. GAEBLER, E. MUNTWYLER, and V. C. MYERS (*Arch Int Med*, July, 1928, p. 79) have studied the alterations in the blood chemistry caused by the treatment of peptic ulcer by alkalis, the result of using various alkalis in routine treatment, the effect of vomiting and aspiration of large quantities of gastric juice, and the shift of the acid base balance after relief of pyloric obstruction by gastro-enterostomy. The investigations of the blood chemistry in a few conditions other than ulcer of the stomach and duodenum—namely, carcinoma, colitis, and pernicious anaemia—were of interest because these conditions had features in common with certain forms of peptic ulcer. In patients showing symptoms of alkalosis changes in the blood chemistry and symptomatic relief occurred when sodium bicarbonate was replaced by calcium carbonate, the only disagreeable result of the administration of calcium carbonate was a tendency to constipation with hard, dry, lumpy stools occasionally producing faecal impaction. The chief symptoms observed were headache, drowsiness, anorexia, nausea, vomiting, muscle ache, nervousness, and mental depression, usually appearing from the sixth to the eighth day. Such symptoms increased during the day as the blood became more alkaline, returning to a more normal condition in the morning before the administration of alkalis was resumed. From a study of forty six patients suffering

from gastric or duodenal ulcer, with special reference to the acid base balance, a definite correlation was found to exist between the alkalaemia in these cases and a group of clinical symptoms chiefly nervous in character. Pyloric obstruction is an important factor in the production of alkalosis, and its surgical relief restores the acid base balance and the chloride deficit. The authors found that when calcium carbonate and magnesium oxide were given without soda the alkalaemia was much less severe, the clinical symptoms of alkalosis were not likely to appear if there was no occurrence of obstruction or vomiting, and in those cases there was no evidence that the alkalaemia produced any renal damage. The importance of treatment with water and sodium chloride, especially as a pre-operative and post-operative measure, is emphasized. It is added that when patients who have been treated with alkalis consent to operation the alkalis should be omitted for several days before operation and water and sodium chloride given freely.

249 Treatment of Acute Poliomyelitis

P. NOBECOURT (*Journ de Méd de Paris* June 7th, 1928, p 447), who has treated six cases of poliomyelitis in children with Pettit's serum, found that it did not prevent death in one case, although it was given as early as fifteen hours after the onset. It had also no effect on the course of the other five cases, even though one of the patients was given as much as 500 ccm of serum. He appends the following instructive statistics of the results of various methods of treatment. Tinel-Giry (*Thèse de Paris* 1911)—Ordinary methods, deaths, 6 per cent, complete or almost complete recovery, 14 per cent, considerable improvement, 68 per cent, persistence of severe paralysis, 12 per cent. Salanfor (*Thèse de Paris*, 1917)—Treatment with convalescent serum, deaths, 22 per cent, complete or almost complete recovery, 30 per cent, considerable improvement, 37 per cent, no change, 8 per cent. Nobecourt's principal conclusions are as follows: (1) Holne-Medlin's disease may assume very different clinical forms, attacks of varying degrees of severity being found in different epidemics, in the same epidemic, and among sporadic cases. Even extensive paralysis may undergo considerable spontaneous improvement. There does not appear to be any specific treatment in the acute stage at the present time, Pettit's serum in particular having no obvious value. Although we possess no really efficient method for controlling the course of Holne-Medlin's disease in the acute stage, considerable benefit may be derived later from the application of various physiotherapeutic measures.

Laryngology and Otology.

250 Abductor Paralysis of the Larynx.

J. E. MACKENTY (*Arch of Oto Laryngol*, July, 1928, p 37) has devised a simple operation for the relief of abductor paralysis of the larynx—a small permanent opening in the windpipe where it dips backward into the thorax. Through a two-inch incision in the middle of the neck the thyroid bridge is excised, and an oval section of the trachea wall is removed, leaving the mucous membrane intact. Skin flaps are nailed with the edge of the oval opening in the trachea. The diaphragm of mucous membrane is left intact for four or five days, after this it is split in its long axis and attached to the edge of the skin flaps. During the period of healing and contraction a small silver obturator is worn or a small tracheal cannula may be substituted. The air passing through this small opening in the trachea counteracts the inspiratory pull on the cords and acts as a safety valve during the dangerous asphyxial spasms. After several weeks the obturator can easily be removed, but if the opening shows a tendency to contract it should be dilated. The operation is not intended to supplant ventriculocordotomy, but may be used as an intermediate procedure between this and tracheotomy. Low speech is possible without closing the aperture, and loud speech can be obtained by pressing the clothing of the neck against the opening. If the laryngeal condition improves, or if ventriculocordotomy is contemplated the tracheal opening is easily closed by eversion and sewing the skin over it. The author adds that this procedure has been found most useful in the case of bilateral abductor laryngeal paralysis.

251 Hypertrophic Rhinitis

L. FELDMAN (*New England Journ Med*, May 17th, 1928, p 682) discusses a rational treatment of hypertrophic rhinitis by the application of the positive pole of a galvanic current to the hypertrophic mucous membrane without producing the bad effects of destruction of excessive tissue. Through a non-vacuum flat nasal electrode held against the tissues a monopolar high frequency current from the Oudin coil is

turned on for about ten minutes and the spark gap regulated so as to produce a slight tingling sensation. This causes hypnomania of the previously pale boggy hypertrophied membrane and renders it ready for the subsequent treatment with current from the positive pole of a galvanic apparatus, attached by an insulated wire to a flat copper electrode covered with cotton. It is moistened and applied intranasally against the tissues, while a larger indifferent moistened pad is placed over the sternum. The average dosage is about three to eight milliamperes applied for about ten minutes, and the whole process is then repeated on the other side of the nose. In 50 cases so dealt with the average number of treatments was ten at forty-eight-hour intervals, 56 per cent of the cases were cured, 24 per cent improved, and 20 per cent unimproved. Goldman considers that this method offers a greater percentage of relief and cure than others, and he is of opinion that further research will prove the value of such physical measures in many chronic and acute conditions.

252 Antral Suppuration Treated by Suction

T. LKJUND (*Umska Läkarsälls apets Handlingar*, April, 1928, p 287) describes how he treated himself for suppuration of the right antrum associated with general and severe local symptoms. Wishing to avoid an operation followed by prolonged irrigation, he constructed a suction apparatus, connected at one end with a vacuum cleaner, and at the other with the antrum by means of a suitably shaped nozzle. From this nozzle a thick walled rubber tube passed to a glass tube thrust through the cork of a wide necked bottle. Through the same cork another glass tube was passed, and was connected with the rubber tubing attached to the vacuum cleaner. When the nozzle was inserted in the right nostril, the left one was closed, the vacuum cleaner was set in action, and the patient was made to close the nasopharynx by trying to breathe through his nose. The vacuum cleaner being always in readiness, the whole operation took only a few moments, and was repeated at intervals. At the end of the operation the nozzle was put into water, which, being sucked into the bottle, cleaned the tubing. During the acute stage of antral suppuration it is necessary to repeat this operation every two or three hours if the pain and sense of pressure associated with this condition are to be avoided. In the author's case this condition cleared up within three weeks, during which he was able to remain at work. The only objection to this treatment is the noise of the vacuum cleaner, which, if worked at night, is liable to be a nuisance to the neighbours.

Obstetrics and Gynaecology.

253 Vaginal Hernia.

J. C. MASON and H. E. SIMON (*Surg, Gynecol and Obstet*, July, 1928, p 36), who record five illustrative cases in women aged 44, 42, 65, 39, and 57 respectively observed at the Mayo Clinic, state that vaginal hernia is very rare. It is formed by a portion of the abdominal contents pushing through an opening in the pelvic floor or a peritoneal sac which presents in the vagina. The symptoms are not characteristic, and the diagnosis is rarely made before operation. When the hernia is large it may interfere with walking. On superficial examination a vaginal hernia is not readily differentiated from a rectocele or a cystocele, but its true nature is usually revealed by more careful examination. Anterior vaginal hernia is distinguished from cystocele by the introduction of a sound into the bladder, while posterior vaginal hernia and rectocele are differentiated by rectal examination, which shows that the bulging of the rectum into the vagina, no matter how marked, constitutes only a small portion of the mass. Complications are rare. Strangulation is uncommon, because the neck of the sac is usually very large in proportion to its size. The posterior type of vaginal hernia is the commonest, being about sixteen times as frequent as the anterior type. The most probable cause of vaginal hernia is congenital weakness of the muscles which form the pelvic floor. Treatment is surgical, the use of palliative measures such as supports of various types being unsatisfactory.

254 Presentations of Sinciput Face and Brow

F. DEMUTH (*Zentralbl f Gynäk*, June 30th, 1928, p 1653), states that presentation of an imperfectly flexed vertex was noted in 1.16 per cent of 12,100 births in a Prague clinic. The 141 cases comprised 77 sinciput, 56 face, and 8 brow presentations. The general conclusion drawn with regard to treatment is that the greatest importance should be attached to early diagnosis. Each case demands a careful consideration of the attendant obstetric circumstances as regards both mother and foetus, but whenever possible expectant treatment is called for. Persistence of sincipital presentation was almost twice as frequent among primiparae as among

multiparae, and the second or right sinclipto anterior presentation was almost as common as the first. In four fifths of cases the foetus was of modicum weight or was undelivered. Pelvic contraction was present in one third, usually as a minor degree of flattening. Three quarters of the sincliptal presentations came to spontaneous delivery, but in both multiparae and primiparae the average time of labour was almost double that of occipital presentations. One fifth of the cases called for forceps delivery, of the 77 cases bipolar version was performed in one and Caesarean section in three. In the whole series the maternal and foetal mortality rates were 1.7 and 3.8 per cent respectively, puerperal fever was present in 14 per cent. Face presentation, of which the first was twice as common as the second position, was more frequent among multiparae, in almost one half of cases a slight degree of pelvic contraction, usually flattening, was present. The foetuses were as a rule small. Of the 56 cases 53 were delivered spontaneously, with a foetal mortality of 16 per cent, the three cases of forceps delivery (on maternal indications) led to three foetal deaths. Death of the foetus almost always occurred during the actual delivery of the head, as a consequence of compression of the cervical blood vessels, it is pointed out, however, that this circumstance affords no indication to instrumental acceleration of delivery, which is attended with an equally large foetal mortality and increased danger for the mother. There were eight persistent brow presentations, in eleven other cases this presentation became changed into face presentations, spontaneously or after treating the mother by laying her on the side corresponding to that of the foetal chin. The average duration of labour was forty one hours, three cases were delivered spontaneously, with one foetal death. Operative delivery was performed in five cases, four times because of maternal pyrexia, four forceps deliveries led to two stillbirths, and one oriotomy was required. One maternal death occurred. Demuth suggests that in unfixed brow presentations (1) oriotomy by manual endeavour and/or positional treatment of the mother, and in fixed presentations with even slight pelvic contraction, (2) the performance of Caesarean section, might diminish maternal and foetal risks.

255. Puerperal Hemiplegia.

N J EASTMAN (*Amer Journ Obstet and Gynecol*, June, 1928, p 753) records seven illustrative cases of puerperal hemiplegia seen at the Pekin University Medical College Hospital in the course of four years. Two were apparently due to cerebral haemorrhage, two to cerebral thrombophlebitis, and three to cerebral embolism. Eastman states that puerperal hemiplegia from cerebral haemorrhage usually comes on during or shortly after labour, probably as the result of a coexisting toxæmia of pregnancy which produces structural damage of the vessel walls, rupture of which occurs owing to the rise of blood pressure and heaving down efforts incident to labour. Puerperal hemiplegia from cerebral thrombosis, which is probably the commonest type of the condition, appears most often in the second or third week of the puerperium, probably always secondary to a pelvic infection. In many instances the cerebral thrombosis is preceded by a toxæmia of pregnancy in which, as in cerebral haemorrhage, vessel damage plays an important etiological part. Certain changes in the colloidal state of the blood increase the tendency to thrombosis in the puerperium. Puerperal hemiplegia from cerebral embolism may be due either to detached ovarian vegetations or to emboli of pelvic origin. Although Eastman's patients all survived, the prognosis of puerperal hemiplegia is usually grave. Cerebral haemorrhage occurring during labour is particularly likely to be fatal. Survivors seldom escape a certain degree of permanent paralysis. Of Eastman's patients only one made a complete recovery.

Pathology.

256. Passage of Living Bacteria through the Intestine.

L ARNOLD (*Amer Journ of Hygiene*, July, 1928, p 604) has tried to determine the factors concerned in the passage of non-pathogenic bacteria through the wall of the intestine. A cannula was placed in the thoracic duct of a dog under local anaesthesia, and lymph was collected with sterility precautions for five minutes. The duodenum was then exposed through a small incision in the anterior abdominal wall, and bacteria suspended in various media were injected directly into it. The duodenum was replaced in the abdomen and the incision closed. Lymph was collected from the thoracic duct, and distributed each five minutes into separate tubes 0.25 c cm was plated on agar, and counts were made after twenty four hours, the bacteria used being *B prodigiosus* and *B coli*. It was found that when the suspending fluid was an alkaline phosphate buffer solution of pH 8.0 or neutral saline solution no bacteria appeared in the lymph, but if

egg white was added to the alkaline solution, then as many as 500 to 1,000 bacteria per c cm of lymph were demonstrated. The addition of egg white to neutral saline had no such effect. The addition of dog's serum either to the alkaline or the neutral solution likewise had no effect. A 10 percent solution of dog's bile in a neutral solution allowed a few bacteria to pass through the intestine and in an alkaline solution definitely more. In all instances in which bacteria did pass through the intestine the passage lasted for not more than an hour, usually for not more than half an hour. Further experiments made on dogs with gastric and cesal fistulae showed that after a high protein meal, given by the mouth *B prodigiosus*, which had been added to the meal, appeared in large numbers in the caecum, after a simple meal of milk, on the other hand, only very few organisms appeared in the caecum. Similarly fever, a high external temperature, or the injection of foreign protein allowed a large percentage of the ingested bacteria to reach the caecum. The author concludes that each factor as these, and the ingestion of large quantities of protein or the sudden alkalization of the upper part of the intestine in the presence of foreign protein, interfere with the normal bacteria killing power of the intestine, as a result of this, bacteria are in certain circumstances able to pass through the intestinal wall and reach the blood stream.

257. Reaction of Guinea pigs to Typhus

H MOOSER (*Journ Amer Med Assoc*, July 7th, 1928, p 19) found that male guinea pigs inoculated with blood from patients with Mexican typhus (tabardillo) almost invariably developed a scrotal swelling, sometimes simulating in many respects the scrotal lesions seen in guinea pigs inoculated with Rocky Mountain spotted fever. Histological examination of the animals inoculated with Mexican typhus shows pronounced swelling and proliferation of the endothelial lining of the tunica vaginalis. The endothelial proliferation is usually so pronounced that the tunica is transferred into a thick oedematous milky membrane, which can easily be scraped off. Smears from the scrapings invariably showed swollen endothelial cells containing minute diplobacilli, often in enormous numbers. These endothelial cells closely resemble the epithelial cells of the stomach of infected lice. The swollen tunica of the guinea pigs is highly infectious, a small drop of the oedematous fluid being sufficient to infect a guinea pig.

258. The Malignant Functions of the Chorionic Epithelium.

W BLAIR BELL (*Journ Obstet and Gynecol of the British Empire*, Summer Number, 1928, p 233) summarizes his view that the chorionic epithelium is originally malignant in nature but is early controlled by the foetus, and that in somatic malignant neoplasia the reversion from highly differentiated to simple cells is to those of the trophoblast. At an early stage the cells of a malignant neoplasm resemble those of the affected tissue, later they revert to a primitive type of cell and even to a synzytial arrangement. Such simple cells, unlike the fully differentiated, take no part in bodily functions, they are "injured" cells whose metabolism changes to meet some abnormal condition such as imperfect oxidation. On comparing the chemistry and functions of normal, benign, and malignant tissues and of the chorionic epithelium, permeability of the cell membrane to water soluble substances is seen in rapidly growing tissues, and is favoured by a high phosphatid cholesterol ratio in the constitution of the membrane, in both these respects chorionic epithelium shows even higher figures than malignant neoplasms and more resemblance to this tissue than to either benign or normal growth. The metabolism of malignant tissues differs from normal and benign in regard to glycolysis, this normally occurs to any extent only in growing tissues. In malignant neoplasms glycolysis is increased, and occurs even in aerobic conditions. Experiments on human placental tissues show glycolysis resembling that in malignant tissue, where chorionic epithelium was present, and a like resemblance is found in the infiltration of other tissues by chorionic villi. On examining the glucose and lactic acid values of maternal and foetal arteries and veins, it was found that the placental circulation had a lower glucose and a higher lactic acid content than in the venous circulation of the mother, this suggests again the high glycolytic power of the chorionic villi, but at full term it may be due to other causes. Like malignant tissues the chorionic epithelium shows a pH value on the acid side of neutrality, and this is more acid the younger the placenta. Chorionic epithelium is thus shown to bare the characteristics of malignant tissue, and this is most marked in its early stages. Conversely, malignant neoplasia of somatic tissues appears to be a process of cellular dedifferentiation back to the trophoblastic type which possesses a metabolic function (glycolysis) that provides energy for existence in abnormal circumstances, such as deprivation of oxygen.

259 J. L. RICHARDSON and M. A. MANKINSON (*Intern Jour Med Sci*, August, 1928, p 168), whose observations are based on 198 cases of alcoholism treated at the Lakeside Hospital, Cleveland, from 1921 to 1926 inclusive state that since the advent of prohibition alcoholism presents many differences from that of former years, its chief characteristics now being early loss of consciousness in a large percentage of cases, a slight febrile reaction, and a transient albuminuria, in addition to other signs of alcoholic intoxication. The 198 cases were classified as follows: acute alcoholism 51, chronic alcoholism 61, neuritis 18, cirrhosis 14, delirium tremens 5, alcoholism associated with other poisons 5, and alcoholism in connection with accidents 44. The rarity of delirium tremens is attributed to the fact that the dolly "tippler" has disappeared and has given way to an individual who indulges in frequent sprays. Alcoholic neuritis is at present characterized by its comparatively rapid onset and short duration. Weakness constituted the complaint in over half the cases, while only one third complained of pain. According to the author's experience the present picture of alcoholic cirrhosis is essentially the same as before prohibition. Of 134 patients admitted to hospital 8 died, 4 from acute alcoholism with complications (namely, cerebral haemorrhage, lead encephalopathy, diabetes, and colitis), 3 from cirrhosis, and one from wood alcohol poisoning.

W. T. VAUGHAN (*Science*, July 6th, 1928, p 1) regards the study and treatment of allergic diseases as primarily a biologic problem, and considers the basic cause of hay fever and asthma to be the inhalation, ingestion, and absorption of some foreign protein through the respiratory or gastro-intestinal mucous membrane. An individual who has become sensitive to the proteol of a food has the barriers against its subsequent absorption much diminished, so that the protein passes through into the circulation without being completely digested. In treatment it is primarily essential to discover the protein to which the patient is sensitive and obtain relief either by avoiding such particular food, pollen, etc., or by producing a gradual desensitization or immunization by repeated injections of increasing doses of the proteol. The search for the causative protein is often tedious, it being not infrequently necessary to try a hundred or more different proteins before all the possible causes for allergic manifestations have been eliminated. While relief may sometimes be obtained by simply avoiding the offending protein, the majority of hay fever patients require desensitization, and from 75 to 100 per cent relief may be expected in most cases. Vaughan lays down the general principle that, as causative agents in hay fever and asthma, the brightly coloured plants are less important than those without brilliant flowerings, and that roughly there are three hay fever seasons—namely, early spring for tree pollens, early summer when the grasses are pollinating, and autumn when the compositae—particularly the ragweeds—are shedding their pollen.

261 A. BUSCHKE (*Med Klin*, July 6th, 1928, p 1042) refers to a number of cases of thallium poisoning, occurring either in industrial processes or when the metal was employed medicinally. Several cases occurred in a factory in which a thallium compound used as rat poison was made. Other cases of poisoning were also reported last year from chemical works where thallium is extracted from sulphur residues. In one week a foreman and five workmen were poisoned, they complained of lassitude, anorexia, pains in the knees and loss of hair. In one case total alopecia was accompanied by distinct erythema of the entire scalp. In every instance eosinophilia and lymphocytosis were present. In two cases albuminuria accompanied by the presence of leucocytes and red corpuscles in the urine, occurred. One patient suffered from severe retrobulbar neuritis, and was quite incapacitated at the end of three months. Papillitis was present, with central scotomata for red and green. The visual acuity deteriorated so that he could count fingers only at nine feet. The patellar reflex was absent. Optic neuritis was followed by optic atrophy. Buschke's observations and experiments have convinced him that cases of industrial thallium poisoning are much more numerous than has been thought hitherto.

The Prussian Ministry of Health has added thallium to the list of dangerous chemicals. In view of the fact that thallium salts are being extracted in increasing quantity from sulphur and lead residues, not only for therapeutic use but also for employment in the manufacture of heavy optical glass, and also that thallium is being substituted for boron in rat poison, Buschke remarks that it is very important that toxic symptoms should be recognized at their commencement. He finds that ocular lesions (optic neuritis, cataract, and iritis) occur as serious complications in many cases after the employment of thallium in the treatment of tinea microspora, favus, and trichophyton. Moreover, when optic neuritis occurs the damage is irreparable. Buschke thinks it is probable that some fatal cases of thallium poisoning in which albuminuria occurred are due to traces of lead which are found frequently in specimens of thallium. He adds that these facts show that thallium therapy demands great care, and that a minimal accurate dosage should be employed.

L. PICCHINI (*Arch di Patol e Clin Med*, May-June, 1928, p 289) gives his experience in some 500 cases of porcnasion over the apices, with especial reference to the changes in resonance which occur when the head and neck are moved in different positions. He describes fully four different positions and illustrates the places where he percusses. The main result of his investigations is to show that in normal conditions the line of resonance is shifted when the head or neck is moved, whereas when there is disease of the apex no shifting of the line of resonance occurs. The apical disease need not be tuberculous, but the author states that this unchanged position of resonance may be an early sign, and be present before more definite signs of tubercle can be detected. The mechanism by which these changes in resonance are brought about is said to be complex, involving many anatomical structures (muscles, aponeuroses, ligaments, bone, articulations, pleura, and lung), and affecting the dome of the pleura and the apex of the lung. The author shows by drawings the site and change in position of the resonant area.

L. H. ZIEGLER (*Journ Amer Med Assoc*, July 31st, 1928, p 138) made a study of the subsequent history of 752 patients who had been treated in the Mayo Clinic for epidemic encephalitis, the average duration of the disease being five and a half years. The occupation, age, and sex did not apparently bear any relation to the severity of the disease. The mortality was 13.2 per cent, and the recovery rate 1.3 per cent about five and a half years after the onset of the disease. Of the entire series 15.7 per cent were able to work regularly and 25.7 per cent were doing light work or part-time work. It was found that patients recovered from severe attacks, respiratory symptoms, and from behaviour or residual sequelae, but rarely, if ever, from the Parkinsonian syndrome, although it might become arrested.

M. HARBIN (*Surg, Gynecol and Obstet*, August 1928, p 155), from a consideration of derangements of the knee joint, advocates immediate suture of complete lacerations of the internal lateral ligament and of tears in the capsule, rather than treatment by fixation with plaster or splints. For an injury producing only effusion without any increased range of lateral mobility, treatment by a short period of rest, followed by physiotherapy, is suitable, but when this range of mobility is 15 degrees greater than that of the other knee, severe laceration or a complete tear of the lateral ligament exists. With such a condition there is the possibility of an interposition of fat or fascia interfering with union and since there may also be damage to the semilunar cartilage, which can only be determined by exploration, immediate approximation of the torn structures is advisable. Rupture of the crucial ligaments does not appear to interfere with function, provided that no obstruction to complete flexion or extension is present, and in the presence of a laceration of the internal lateral and anterior crucial ligaments early repair of the internal lateral ligament renders the joint stable. The tear is usually a sharp transverse one, which is easily approximated, and such immediate repair gives more satisfactory results, with a shorter period of disability, than when the

ropoli is delayed. In a case in which laceration of the posterior cornua of an internal semilunar cartilage caused constant pain, even with the joint fixed, complete relief followed removal. Harlin reports cases in which the removal of loose bodies in the knee joint resulted in complete return of function. In one case of villous osteo arthritis and hydrops the pain and swelling of the left knee were relieved by synovectomy.

285 Bone Marrow Transplantation in Bone Diseases

M. KATZENSTEIN (*Zentralbl. f. Chir.*, July 28th, 1923, p. 1872) agrees with those who regard the pathology of Porthos' and Köhler's and a few other diseases as of the nature of a localized necrosis of bone marrow associated with defective powers of regeneration in the surrounding marrow, whether this is due to embolism or to trauma is still uncertain. When weight is put on the limb, however, deformity involving the neighbouring joint ensues. In several cases in which the usual forms of treatment had failed the author has treated the condition by an autogenous subperiosteal bone marrow graft. Bone marrow is removed from the tibia by gently raising a flap of bone, which is left attached at one end and introduced under the cartilage at the site of the defect, the limb is then put up in plaster for about two months. Satisfactory anatomical and functional results from this procedure are reported. In one case of disease of the left hip joint with a five years' history of treatment, the patient was subsequently free from pain and able to walk without a limp, there was no shortening, and the range of movement at the hip joint had considerably improved.

286. Treatment of Burns.

F. CHRISTOPHER (*Amer. Journ. Surg.*, July, 1923, p. 61), discussing the modern methods of treating burns, advises that, when one-tenth or more of the body surface is involved, shock should first be treated by morphine, external heat, and fluids, and possibly by blood transfusion. As soon as possible gauze saturated with 2½ per cent tannic acid solution is applied, and the area is kept moist with this solution for twenty-four hours until it is thoroughly tanned. The burned area is then treated by the open air method under a heated oradle. Fluids are pushed and blood transfusions are given if necessary. When all sloughs have disappeared, and the wound is cleanly granulating, adhesive or rubber tissue strips are applied, and scarlet-red preparations are used to accelerate epithelialization. Skin grafting is occasionally advisable. Tannic acid appears to exert its beneficial action by fixing the toxic substances in the burned tissue. For small burns involving less than 5 per cent of the body surface the application of soothing ointments containing phenol or picric acid, and gauze dressings, is the best treatment.

287. Carcinoma of the Pancreas.

As the result of a study of 37 cases, J. FRIEDENWALD and T. S. CULLEN (*Amer. Journ. Med. Sci.*, July, 1923, p. 31) conclude that carcinoma is the most common malignant tumour of the pancreas. It occurs usually between the ages of 40 and 70, and is more frequent in males. In primary cancer the head of the pancreas is its most frequent site and the growth, usually of the sclerous type, is characterized by enlargement with nodulation. Compression of Wirsung's duct induces an interlobular pancreatitis, which may destroy the islands of Langerhans, with resulting glycosuria. The common duct and pylorus may become involved, in the latter instance pyloric stenosis with gastric dilatation ensues. The onset is usually gradual, and the initial signs are vague. At first only mild symptoms of indigestion are noted, but these soon become exaggerated, and pain, vomiting, deepening jaundice, loss of flesh, and oedema are added. When these symptoms occur in a patient past the age of 50 pancreatic cancer should always be suspected. Pain is a characteristic symptom, though in rare cases it may be entirely absent. Tenderness on pressure over the epigastrium is frequent, and jaundice is very common, the latter increases progressively until the skin assumes a black line and then gastric and intestinal haemorrhages are not unusual. The gastric secretion frequently contains no free hydrochloric acid, and the stools are usually soft and contain an abnormal amount of fat and undigested muscle fibres. The pancreatic secretion ordinarily shows a diminished activity, and often a complete absence of ferment, especially of protease. Enlargement of the liver is frequent, and a pear-shaped distension of the gall bladder is of great diagnostic importance. Transient or permanent glycosuria indicates an advanced stage of the disease. Ascites and oedema of the extremities may occur as late complications, and pressure of the growth on various organs may cause symptoms of obstruction. Diagnosis is easy in about half the cases, in others it is extremely difficult, and often the differential diagnosis between malignancy and chronic pancreatitis is

impossible. The duration of the disease varies from a few months to two to four years, depending on the rapidity of the growth, its interference with other organs, and subsequent complications. The prognosis is grave, and there is little hope of radical cure. Cholecystostomy, gastro-cholecystostomy, and gastro-cystenterostomy may afford temporary relief.

Therapeutics.

288. Liver Extract in Sprue.

W. RICHARDSON and T. G. KLUMPP (*New England Journ. Med.*, August 2nd, 1923, p. 215) report a case of sprue treated with liver extract, the daily ingestion of this gave results comparable to those in similar cases fed with large amounts of whole liver. A man, aged 59, was admitted to hospital complaining of weakness, loss of weight, and diarrhoea of five years' duration, with periods of partial recovery followed by relapses. The stools were typical of sprue, they were loose, bulky, mushy, yellowish, and full of gas bubbles and fatty acid crystals. There was severe anaemia indistinguishable from the pernicious form, with marked oematocrit, and a large amount of free hydrochloric acid was present in the stomach contents. The response to liver extract was most striking: a red cell count on admission of 376,000, of which 2 per cent were reticulocytes, rapidly improved, the reticulocytes began to rise on the third day, and reached a peak of 37 per cent on the seventh day. Rapid improvement also occurred in the gastro-intestinal symptoms, the stools becoming normal by the ninth day, the improvement in this blood picture was typically that which results from liver extract treatment in pernicious anaemia. The authors add that the accompanying rapid improvement in the gastro-intestinal symptoms suggests the possibility of pernicious anaemia being a symptom of the lack of a specific substance due to some gastro-intestinal disturbance, and that their case points to the fact that the use of liver extract can relieve the associated anaemia as well as the digestive symptoms of sprue.

289. Diet in Gastro-duodenal Ulcer.

LEON MEUNIER (*Presse Méd.*, August 11th, 1923, p. 1020) states that gastric ulcer may slowly develop for twenty or thirty years, and that during this time long periods of freedom from symptoms occur. During these it is impossible to impose a very strict, irksome regimen, but at the same time the patient should not be allowed an unrestricted diet. To overcome this difficulty the author progressively increases the food, and introduces variations. The three chief kinds may be given (nitrogenous, starchy and fatty), attention being directed rather to their preparation than to their chemical composition. Gastric secretion can be lessened by modifying gustatory sensations through the diet. Such sensations are more or less caused by salts, sugars, spices, acids, and bitters, which should therefore be avoided. Aromatic substances also should be eliminated. Hence meat should be boiled, rather than stewed or grilled, and insoluble starches are preferable to sugars. Since the longer food remains in the mouth the greater the gustatory sensations excited, the diet should be chiefly liquid or finely minced, and consist of soups, milk, minced boiled meat, boiled fish, dried vegetables in purées, and minced greens. Bread and biscuits, since they need mastication, should be avoided. A diet of this nature diminishes salivation also, so the patient should drink at meals sugar-converting liquids, such as grumulated barley water, the action of which replaces that of the saliva. Every week there should be a physical and alimentary rest for twenty-four hours, for that length of time the patient should remain in bed or on a couch, with a hot bottle over the gastric region after each feeding to increase gastro-duodenal peristalsis, the food should be liquid or semi-liquid and taken over three hours. The patient should be advised to live exactly as during a painful crisis. By this intermittent rest the author believes that these crises can always be retarded and often checked, thus obviating surgical intervention.

290. The Toxicity of the Colloidal Sulphides of Heavy Metals.

The therapeutic value of a number of the heavy metals has long been recognized, but since in some cases the colloidal preparations of these have proved as toxic as the crystalline, G. E. WAKERLIN and C. TISEMAN (*Amer. Journ. of Syph.*, July 1923, p. 384) have carefully studied the toxicity for rabbits of colloidal solutions of the sulphides of several heavy metals. The colloids of mercuric sulphide, copper sulphide, bismuth sulphide, mercurous copper sulphide, sulpharsenite, bismuth sulphide, and stannous were tested, the mercurous copper sulpharsenite, and stannous were tested, the maximum amount tolerated and the minimum lethal dose

being ascertained for each. The protective proteins used in the preparation of these colloidal solutions were proved to be non-toxic in the quantities employed and apparently devoid of anaphylactic properties; the solutions remained stable for the two-month period of the experiments. None of the colloidal solutions produced objective irritant effects at the site of injection into the marginal ear vein, there being no local venous thrombosis, inflammation, or sloughing, comparatively large doses of colloidal lead and gold sulphides and metallic gold caused no bad effects in dogs. Colloidal lead sulphide was found to be less than one-thirtieth as toxic as the preparations used by Blair Bell and Wood in treating cancer, and colloidal gold sulphide and metallic gold much less so than sanocrysin. The authors believe that these preparations are relatively non-toxic, and may prove to be of great value in the treatment of cancer, syphilis, tuberculosis, and other diseases.

271 Serum Treatment of Erysipelas

W. S. McCANN (*Journ. Amer. Med. Assoc.*, July 14th, 1923, p. 78), who reports a series of cases treated with serum and controls, maintains that the true value of the serum treatment of erysipelas will not be established until an analysis can be made of a long series of cases with simultaneous controls not treated by the serum. Previously published reports of the results of serum treatment are open to serious objections on the score of inadequate control. The cases reported by McCann do not prove that erysipelas serum is of no value, but merely indicate that a comparison of them with statistics of cases admitted to hospital in the eleven years prior to the introduction of the serum treatment is most unfavourable to the use of serum both as regards mortality and the duration of stay in hospital. Skin tests indicated that if erysipelas serum was of value a scarlet fever antitoxin was also valuable in the treatment of erysipelas.

Disease in Childhood.

272 Cyclical Vomiting in Children

G. LEVEN (*Bull. Soc. de Théor.*, June 13th, 1923, p. 150), who records two illustrative cases in boys aged 10 years, maintains that cyclical vomiting in children, with or without acetonaemia, is in the great majority of cases ordinary dyspeptic vomiting, which is caused or aggravated by aerophagia. In rare cases atonic dilatation of the stomach complicates the clinical picture. In all cases of cyclical vomiting in children a search should be made for clinical signs of aerophagia both by clinical and radiological examination. Treatment consists in the administration of a mixture containing sodium bromide and lithium carbonate, and respiratory exercises.

273 Spina Bifida Occulta

G. LATTES (*La Pediatria*, May 15th, 1923, p. 531) reviews recent work in reference to spina bifida occulta. After discussing the anatomical varieties and pathology, he describes the local and distant signs and symptoms. His comments on the frequency with which enuresis occurs as a symptom, and remarks that in any cases where this is prominent and cannot be explained otherwise it is well to think of the possibility of spina bifida, and if necessary employ radiography or inject lipiodol. In some instances, by freeing adhesions or cyst-like tumours at an early stage, it is possible to prevent the development of the paralysis and sensory or trophic changes which often appear subsequently.

274 Treatment of Intussusception

E. EDBERG (*Acta Paediatrica*, August 15th, 1923, p. 130) discusses several recent papers on this subject, and concludes that surgical treatment offers more hope, especially if carried out early than non-operative mechanical taxis. Many patients are not brought to the surgeon until gangrene and peritonitis have set in. In the etiology of the disease he attaches importance to the lymphatic system, especially the lower Peyer's patches, as being the primary cause of invagination in some cases, pointing out that intussusception often follows an enteritis accompanied by an acute swelling of the lymphatic glands, especially in the lower portion of the small intestine. As regards Meckel's diverticulum, he doubts whether the usual view holds good, and describes a case where invagination of the ileum probably began circularly at the very place where the top of the long, wholly inverted diverticulum was situated. The author states that the only type of case where surgical treatment should not be resorted to at the outset is that in which the exact onset of the illness is known, and which affects only the colon or is ileocaecal. Here mechanical means may be tried, especially if

the child is not very young, x-ray examination with opaque injection may be very useful during replacement and as a control. Details of 67 cases are given in tables which are classified as follows (the tumours in parentheses refer to deaths in each case): Ileac, 4 of which were due to Meckel's diverticulum, 9 (7), ileo colic 18 (11), ileo colic or ileo-caecal 2 (0), ileo caecal 28 (5), colic 10 (1). The total was 67 (24). Two other patients succumbed after operation, but from other causes.

Obstetrics and Gynaecology.

275 Insulin Treatment of Uterine Haemorrhage.

H. BULTMANN (*Zentralbl. f. Gynäk.*, July 21st, 1923, p. 1841) states his experience of insulin treatment, as recommended for trial by Vogt, in metrorrhagia haemorrhagica and in menorrhagia accompanying chronic inflammation of the ovaries or uterus. He has found that attacks of excessive bleeding at or shortly after puberty always yield to this treatment. He describes, as an example, the case of a girl, aged 19, whose menses for three and a half years had lasted from two to three weeks, she had been cured four times, and was admitted to hospital with the diagnosis of pernicious anaemia, the haemoglobin percentage being 29. Insulin injections for seven days, repeated after an interval of eight days, led to cessation of bleeding on the third day of the first course and to two ensuing three to four day periods at monthly intervals during her stay in hospital, in the course of which her weight increased by 34 per cent and her haemoglobin to 77 per cent. Climacteric bleedings which did not improve after a previously diagnostic curettage were treated by insulin and showed an improvement, which however, lasted for two or three months only so that x-ray treatment was finally necessary. Menorrhagia associated with chronic adnexal inflammation showed no response to insulin therapy, and cases of so-called chronic metritis, with a large hard, and tender uterus and excessive bleeding not influenced by curettage, exhibited only a transitory improvement. The insulin was injected intramuscularly in doses of 25 units night and morning on the first day, increased to about 45 units night and morning on the fourth day, and thereafter diminished to 25 units twice daily on the seventh and last day of the course. After each injection 40 grains of sugar were given dissolved in a tumblerful of lemon water. No signs of hypoglycaemia were noted in forty cases.

276 Sodium Hypochlorite as a Tissue Disinfectant.

W. O'N. SHERMAN (*Surg., Gynecol. and Obstet.*, July, 1923, p. 115) reports that irrigation of the uterus with sodium hypochlorite solution of low alkalinity, in combination with hypertonic saline solution, destroys bacteria in the uterus and dissolves blood clots, placental tissue, and debris, without destroying the living tissues and leucocytes. His isotonic preparation consists of sodium hypochlorite 0.5 per cent, sodium chloride 0.7 per cent in distilled water. Sherman states that sodium hypochlorite in proper dilution is not toxic and can be used in any quantity, he finds it much more effective than phenol and mercury preparations. He has used as much as 10,000 c.c. in a period of twenty-four hours in the treatment of pyemia, with no deleterious effect. In septic endometritis, whether puerperal or following abortion, the intermittent irrigation of the uterus with a hypochlorite solution has brought about cure, but the author warns against the ill-advised or careless performance of this treatment, since traumatic extension of the uterine infection may follow. He has found it of the greatest value in puerperal septic endometritis of mixed bacterial origin with marked subinvolution of the uterus, but he adds that if extension to the perimetrium has occurred or is expected attempts at the treatment are inadvisable.

277 Cancer of the Cervix Uteri.

K. H. MARTZLOFF (*Surg., Gynecol. and Obstet.*, August, 1923, p. 183) discusses the surgical treatment of cancer of the cervix and the criteria essential to the establishment of a post-operative prognosis. Without belittling radium and deep x-ray therapy, the advantages and limitations of surgery are analysed and the various results compared. A proper selection of patients and an experienced surgeon are essential, in order that a permanent cure may be expected. The question of operability must be determined clinically beforehand by a consideration of the history and of such contraindications as extension of the cancer to the rectum, bladder, or paracervical tissues with regional lymph gland involvement. An adequate operation involves a panhysterectomy with removal of the proximal one-third to one-half of the vagina, and a wide parametrial dissection after the uterers have been mobilized for their distal 10 cm or more. Although some

authorities advocate the routine extirpation of the iliac and contralateral glands, while others recommend the extirpation of the regional lymph glands only when palpably enlarged, most gynaecologists operate without removing them, and this seems to be the most rational basis for surgical treatment. Ethylene carbon dioxide oxygen anaesthesia gives the most perfect relaxation and the best anaesthetic results. As to the post-operative prognosis, extension of the cancer to the uterus alone, while impairing the chance of cure, does not obviate it in spino-epithelial cancer, but in the transitional cell type such extension entitles any such chance. In the adenocarcinoma or in the spindle cell cancer it is not possible to generalize. A duration of symptoms in the spino-epithelial and transitional cell types of more than eight months, or of less in the spindle cell variety, renders cure improbable. The adenocarcinoma is the most hopeful, since 75 per cent of the operable cases may be considered cured. In order to enable a post-operative prognosis to be made it is essential that the tissue removed at operation should be examined to determine the extent of the local neoplastic invasion, the variety of cancer, whether adenocarcinoma or epidermoid carcinoma, and, if the latter, the predominant type of cancer cell. This involves the study of numerous micro sections of the cervical parametrium cut at right angles to the longitudinal axis of the cervix through its entire length, of the thickness of the vaginal cuff, cervix, adnexa, and of the corpus uteri well beyond any macroscopic involvement. Such an examination, together with the fact that an adequate hysterectomy and a wide parametrial dissection are performed by a competent surgeon, affords a rational basis for a prognosis, and Martzloff concludes that in properly selected cases surgery has a definite place in treatment.

278. Carcinoma of the Body of the Uterus.

G. VAN S. SMITH and R. S. GRINNELL (*Amer. Journ. of Obstet. and Gynecol.*, June, 1928, p. 832) report a series of 101 cases of endometrial carcinoma in which the proportion of carcinoma of the uterine body to that of the cervix was 1 to 4.46. Ten patients gave a family history of malignancy, and in 35.6 per cent of the cases there was no history of pregnancy. The symptoms began usually in the sixth decade and after the menopause, they were generally present for about two years before the patient came for treatment; the earliest and most prominent symptoms being bleeding or a blood stained discharge. Fibromyoma was an associated condition in about a quarter of the cases. The operative mortality was 3.37 per cent. The authors consider that an absolute curability of about 20 per cent is approximately correct for carcinoma of the body, as compared with 5 per cent for that of the cervix. This better prognosis is attributed to the late involvement of surrounding structures, the infrequency of metastasis, and the lower degree of malignancy. Radium is thought to be less beneficial in this condition, except as a palliative procedure where an operation either is contraindicated or has failed to extirpate the disease.

Pathology.

279. Calcium Metabolism in Diseases of the Skin.

N. BURGESS (*Brit. Journ. of Derm. and Syph.*, July, 1928, p. 279) has estimated the serum calcium in certain diseases of the skin in which the vegetative nervous system and the endocrine glands are believed to be primarily at fault. The diseases investigated were urticaria, including dermographism and angioneurotic oedema, prurigo of the Besnier type in which lichenoid, asthmatic, hay fever, and eczema are common symptoms, acroasphyxia, including erythema pernio, generalized alopecia areata, eczema, and light sensitization of the adult type. Studies were made of other diseases not having a primary nervous factor, such as psoriasis, seborrhoeic dermatitis, Darier's disease, erythema multiforme, and acrodermatitis continua, and estimations of the serum calcium in healthy persons were also made. In many instances a normal figure for the total serum calcium associated with a diminished amount of precipitable calcium was discovered, and in a few cases of certain skin diseases there was a diminution of both total and precipitable calcium. The great majority of cases of urticaria, especially those with marked dermographism, prurigo of the Besnier type, total alopecia areata, light sensitization of the adult type, and eczema, showed a marked diminution of precipitable serum calcium. One group of cases of acroasphyxia and erythema pernio showed a greatly diminished amount of precipitable calcium, while in another group the serum calcium was normal. In only one case of psoriasis was there diminution of the precipitable serum calcium, and two cases of seborrhoeic dermatitis

with considerable accompanying secondary infection had a lowered serum calcium. A slight diminution of the serum calcium was found in one case of erythema multiforme with normal figures were obtained in a case of Darier's disease and in one of acrodermatitis continua. Burgess found a diminution of the precipitable calcium in the serum with, in most instances, a normal to a calcium content in those cases in which the endocrine glands and the sympathetic nervous system were thought to be primarily at fault. Cases of urticaria, prurigo and eczema, and those cases of acroasphyxia and chilblains with a low serum calcium content, were much improved by treatment with calcium and parathyroid extract. Dysfunction of the endocrine glands apparently leads to an altered chemical or physical state of the serum calcium, causing a diminution in the amount of calcium for use by the tissues, with an increased irritability of the sympathetic nervous system resulting in the formation of skin lesions.

230. Tests of Hepatic and Pancreatic Functional Ability.

E. A. GRAHAM (*New England Journ. of Med.*, July 5th, 1928, p. 1), discussing various functional tests states that out of 2,289 patients examined by cholecystography 264 were diagnosed as having pathological gall bladders, and cholecystectomies were performed, of these 254, or 96 per cent, showed definite evidence of disease. Of 69 cases where the gall bladder was passed by this test as normal, 61 were found by gross examination during operations for other abdominal conditions to be quite normal, 2 were diseased, and 6 cases were doubtful. This gives a percentage of accuracy for this test in the case of the normal gall bladder of over 88, as compared with Kirkin's figure of 69. Graham discusses possible fallacies in this test, and emphasizes its value in indicating the degree of concentrating power and the ability of the gall bladder to empty itself. The excretory function of the liver was tested by Graham, using phenolphthalein in doses of 0.04 gram per kilo of body weight, or eight times the recommended dose. In normal cases about 12 per cent of the dye remains in the serum half an hour after injection, and only 5 per cent after an hour. About 90 per cent of cholecystitis cases, even without jaundice, give an average half hour retention figure of 27 per cent. These results suggest that operation risk is greater in cases with high retention figures, such as 40 per cent and over. Graham adds that the retention figures are relatively low in cases of obstructive jaundice due to malignant disease, and high when there is a stasis in the common duct or "obstructive icterus" is present. The regurgitation of pancreatic secretion into the stomach and the consequent neutralization of the HCl has been estimated by the author in a new type of test meal, in which the time taken to neutralize 200 c.c. of 0.5 per cent HCl introduced into the stomach is measured. He states that this type of test meal has practically supplanted the older kind, and is also used to study the post-operative results of gastro-enterostomies and gastric resections, in which it is of great prognostic value. Importantly attached to the regulation of the acidity of the gastric contents by pancreatic regurgitation, and the existence of the condition termed "hyperacidity" is doubted. Persistence of gastric acidity may be due to pyloric obstruction of mechanical or other nature.

231. The Cerebro-spinal Fluid in Acute Poliomyelitis.

G. M. LYON (*Amer. Journ. Dis. Child.*, July, 1928, p. 40) has investigated the cytology of the cerebro-spinal fluid in the pre-paralytic stage of acute poliomyelitis. His results suggest the presence of some cytolytic factor, not described previously, particularly active towards the multilobed cells. The origin of these cells has not been fully determined, they may be identical with the polymorphonuclear leucocytes of the blood stream, or they may be wandering clasmatoocytes not necessarily of haematogenous origin. The author inclines to the latter view. Proof is given of the advisability of making spinal fluid cell counts immediately after lumbar puncture in all cases in which there may be a possibility of poliomyelitis. A pleocytosis of 50 per cent or more of multilobed cells occurring in a clear fluid is suggestive of acute poliomyelitic infection. Lyon asserts that when, in the course of from twenty-four to thirty-six hours, the lumbar puncture is repeated, and there is a fall in the total cell count with a shifting of the differential count to a mononucleosis of 90 per cent or more, it is certain that the condition is one of poliomyelitic infection. This cellular response is pathogenic, as it has not been observed in the spinal fluid in other conditions. It is not easy to determine the exact mechanism of the cytotoxicity. If there is a cytolytic characteristic of poliomyelitic fluids, it is probable that it does not appear until the time of, or shortly after, the shower of virus into the cerebro-spinal fluid.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

282.

Linear Vaccination

M D MACKENZIE (*Journ Royal Army Med Corps*, September, 1928, p 161) records the results of vaccination among recruits for the army, with special reference to the severity of the reaction and its consequences. He found that single linear (6-7 mm) insertions or four linear marks in primary vaccination or revaccinations were preferable to scarification: no man thus treated had later to be admitted to hospital. Routine exemption from duty or drill did not appear to reduce the severity of the reactions, but rather the contrary. Urticaria and pruritus were greatly diminished when the strapping was replaced by a bandage to secure the dressing. Mackenzie discusses the relation between the degree of immunity and the size of the scars of primary vaccination; he places the primary four scar cases in four groups: (a) those with a total scar area of less than 500 square mm, (b) an area of 500 to 1,000 mm, (c) an area of 1,000 to 2,000 mm, and (d) an area of over 2,000 mm. In these groups there were true vaccinia reactions in 100, 62, 66, and 44 per cent of the cases respectively, but it is added that these figures do not tally with those of other observers, who may have included cases of late vaccination or revaccination. Mackenzie suggests that the acceleration of three days in the time of maximum reaction as a result of primary vaccination represents the average amount of immunity remaining in this age group (18 to 21 years), and gives figures to show that the amount of acceleration of the maximum reaction varies with the scar area of primary infantile vaccination.

283.

Diagnosis of Insulin Coma.

E L SEVINGHAUS (*Journ Amer Med Assoc*, August 4th, 1928, p 305) reports two cases of diabetes mellitus to illustrate the value of clinical observation and testing the urine for sugar and acetone in diagnosing the cause of coma in this condition. In one case—an ambulatory patient—the condition was traced to a dietary indiscretion. In the second patient there was doubt whether a syphilitic infection was present, and the coma followed nervous excitement and unaccustomed exercise. The author remarks that the differentiation of diabetic coma and insulin coma in a known diabetic patient presents an important practical problem, in spite of the fact that in the first instance dehydration, and in the second sweating, is usual. In the first of the author's patients a dry skin was present during coma attacks, which were demonstrated to be hypoglycaemic in nature. The author doubts also whether convulsions form part of the typical picture of diabetic coma. He suggests that when there is doubt as to the nature of the condition there is nothing to be lost, and much to be gained, by giving an intravenous injection of from 10 to 20 c cm of 50 per cent dextrose. In insulin coma beneficial results follow in from one to three minutes, while the diabetic comatose patient does not respond, and no additional harm is caused by the single injection. If the coma does not respond to the dextrose injection within ten minutes, it is then safe to proceed with the usual methods of treatment of true diabetic coma. In the author's second patient, however, insulin coma did not yield readily to this treatment because there was a complicating factor—namely, paraldehyde, which the patient had taken.

284.

The Inheritance Factor in Tuberculosis.

REFERRING to a previous paper in which an analysis was made of the family records of approximately 4,000 tuberculous patients in Belfast and an attempt made to construct tuberculosis life tables for the general population of that city, P STOCKS and MARY N KERN (*Ann of Eugen*, April, 1928, p 63) state that no account was taken of the presence or absence of the disease in parents, grandparents, or collateral relatives, and therefore a further analysis was made on the basis of the antecedent history. From this latter study the authors deduced that the fathers and mothers of tuberculous patients were subject to a higher rate of tuberculosis than the general population of parents, and, conversely, that the children of tuberculous parents were subject to higher rates than the general population of children. The rate in children was more pronounced when the mother rather than the father was affected, and much more so when both parents were tuberculous. These facts could be explained by infection whether inheritance is involved or not, but it can be demonstrated that, whereas in the latter instance the contingency coefficients between pairs of children would be

independent of the condition of their parents or antecedents, this would not be the case if susceptibility to infection is inherited as a quantitative factor. Arranging the families in groups according to the presence or absence of tuberculosis in parents or antecedents, it was found that the contingency and correlation coefficients for pairs of children were greater with increasing tuberculosis in the antecedents, a result to be expected on the theory of inheritance, but inexplicable if susceptibility is independent of the antecedents. The contingencies between non-pulmonary forms of tuberculosis in pairs of siblings also suggested that inheritance must be involved.

285.

The Electric cardiogram in Diphtheria.

M H NATHANSON (*Arch Int Med*, July, 1928, p 45) remarks that though it is generally agreed that involvement of the circulation following diphtheria is of serious import, there is no accurate clinical method for detecting its presence. In fifteen severe and moderately severe cases of diphtheria examined by him with the electrocardiograph, seven showed inversion of the T wave in significant leads during convalescence, and two of these patients died suddenly. In the patients who recovered the inverted T wave returned to normal as early as seven weeks after the onset of the disease. Cats injected with sublethal doses of diphtheria toxin showed consistently similar T wave alterations, usually within forty-eight hours. These observations support the myocardial theory of the circulatory failure in diphtheria, as opposed to the theory of paralysis of the vasomotor centre, or that of a toxic injury to the vagus nerve. Nathanson concludes that electrocardiographic studies are of practical value in diphtheria during the period of convalescence to ascertain both the presence of myocardial involvement and its duration.

286.

Carriers in Vincent's Angina

THE occurrence of a typical case of Vincent's angina in a college led K PARDEE, T F GORDON, and C RILEY (*New England Journ Med*, May 31st, 1928, p 796) to examine smears from the gums or throats of 462 students, and they found numerous fusiform bacilli and spirilla in 139. Mild but definite clinical signs in the form of redness and puffiness of the gums or inflamed throats were found in 113 (82 per cent), but only two developed all the typical symptoms of Vincent's angina. Under treatment with local applications of chromic acid and a mouth wash the majority of cases cleared up in eight days. Moderate smoking apparently did not influence the incidence of the infection, but possibly delayed cure. Good oral hygiene seemed the most important factor in decreasing susceptibility.

Surgery.

287 Late Intestinal Stenosis following Strangulated Hernia

L GINZBURG and E KLEIN (*Annals of Surgery*, August, 1928, p 204) report five cases of late intestinal stenosis as a sequel of operations for strangulated hernia. After intervals ranging from three or four weeks to several months severe abdominal pain developed with an incomplete mechanical ileus. Premonitory symptoms of diarrhoea, or intestinal bleeding due to secondary sloughing of affected areas, may also occur. If the obstruction is not removed the patients go rapidly downhill from starvation, severe anaemia, or chronic toxic absorption. Laparotomy shows either an area of tubular stenosis due to fibrosis of part or all of the strangulated loop, or an annular stricture corresponding to the zone of intestinal constriction at the neck of the sac. The early stages of strangulation show venous stasis, oedema, and some haemorrhagic extravasation in the wall of the affected loop; relief of the constriction results in a return to normal. In the advanced stages there is a progressive devitalization of portions of the affected gut, and thrombosis of the vessels in the intestinal wall or smaller mesenteric radicles causing interference with circulation. These cases undergo perforation even after the constriction is removed. The authors remark that operative intervention should be undertaken early, and should consist of resection of the involved portion of the gut or of a short circuiting entero-anastomosis. If resection is performed a lateral anastomosis is preferable owing to the disparity in the diameter of the proximal and distal loops. In the presence of numerous adhesions, or when the patient is in poor condition, entero-anastomosis is the preferable mode of procedure.

288 Toxic Goutre and Mental Disease

J L DE COURCY (*Arch of Surg*, August, 1928, p 296) discusses the relief of psychoses in thyrotoxic patients by means of thyroidectomy. He believes that thyrotoxicosis may be the exciting or a strong contributory cause of serious mental disease, and that thyroidectomy may offer a good prospect of mental recovery. Out of fourteen cases of insane patients with toxic goutre, all but two recovered sufficiently after operation to resume their former occupations. In the majority of these cases the mental symptoms were previously extremely pronounced, and in two, where a diagnosis of dementia praecox had been made and a poor prognosis given, complete recovery followed operation. In thirteen cases the goutre was of the exophthalmic type, the exception being a toxic adenomatous goutre with evidence of hyperplasia. The author remarks that, when thyroidectomy is performed on patients with psychoses, preoperative rest, medication with a compound solution of iodine, and the most perfect operative technique are even more important than in patients with normal mentality.

289 Calcification of the Gall Bladder

J J ROBB (*Brit Journ of Surg*, July, 1928, p 114) reports a rare case of calcification of the gall bladder accompanied by gall stones. The patient, who was the mother of eleven children had complained of pain for several months in the right subcostal region and also round the medial angle of the scapula, this was accompanied by attacks of nausea without vomiting or jaundice. There was tenderness over the gall bladder. At operation the gall bladder was found to be hard and fixed by periglandular adhesions. Cholecystectomy was performed and the patient made a good recovery. Pathological examination showed the gall bladder to be of walnut shape, measuring 3.6 cm from the fundus to the cystic duct and 2.6 cm transversely. The serous coat was of a dull grey colour, thickened and fibrotic, and it could be stripped cleanly from the wall of the gall bladder. The muscular layer had the appearance of bone, the mucosa had disappeared and had been replaced by a layer of lime salts which encroached the wall of the gall bladder, crossing over and shutting off the entrance to the cystic duct inferiorly, but not extending into it. The gall bladder was filled with laminated calculi, the largest measuring 1.5 cm across, these were cemented together by lime salts. Microscopic examination showed that the mucosa was entirely absent and the muscular stratum had been replaced by an acellular homogeneous substance.

290 Fracture Statistics.

M CAMURATI (*Chir di Org di Movimento*, August, 1928, p 452) reports that the 328 cases of fracture of the bones of the elbow formed 12 per cent of all the fractures treated at the Rizzoli Institute, Bologna, from 1899 to 1926, and 29.54 per cent of the fractures of the upper limb. The most frequent variety was the transverse supracondylar fracture (34.14 per cent), then those of the external condyle (15.24 per cent), internal condyle (11.28 per cent), epicondyle (7.92 per cent), and epitrochlea (6.70 per cent). The male sex was most frequently affected, 218 patients (66.46 per cent) being males and 110 (33.53 per cent) females. The age at which the fracture most frequently occurred was the second half of the first decennium. The mechanism was most frequently (60.67 per cent) indirect violence. Primary nervous lesions were not exceptional, being represented by 20 cases (6.03 per cent), in which isolated lesions of the musculospiral nerve predominated (14 cases). Late nervous lesions, on the other hand, were rare, being represented by only 2 cases of palsy. Fractures of the elbow were accompanied by dislocation in 40 cases (12.19 per cent), the posterior variety being the most frequent (29 cases). Ossification took place in 67 cases (20.42 per cent). The best results were obtained by bloodless methods, by which 135 patients (51.92 per cent) were treated. A SOLDI (ibid., p 466) states that the 186 cases of fracture of the bones of the wrist formed 6.8 per cent of all the fracture cases treated at the Rizzoli Institute in the period named (117 (62.9 per cent) occurred in males, most of whom were affected between the ages of 11 and 15 and 45 and 50, whereas in females the fracture was met with at any age. The Pott's Colles' joint articular type was most frequent (40.86 per cent), while articular fractures represented only 27.68 per cent of the cases observed. Among 161 cases in which the mechanism of the fracture could be ascertained indirect violence was responsible in 152 and direct violence in only 9, including 2 cases of back fire fracture in motor drivers. In both sexes the left wrist was most frequently affected. Nervous complications were very rare, being represented by only one case of laceration of the median and ulnar nerves. In recent fracture bloodless orthopaedic treatment is advised, while operation is indicated in old fractures consolidated in a vicious position, as well as in fractures of the scaphoid and

scapholunar. E DUSI (ibid., p 473) states that the 242 cases of fracture of the neck of the femur treated at this Institute formed 19.16 per cent of the fractures of the lower limb and 64.4 per cent of the fractures of the femur, 136 cases were in males and 106 in females. Of 214 cases of which radiograms were available, 141 (65.7 per cent) were transcervical and 73 (34 per cent) cervico trochanteric. In youth and old age transcervical fracture was commonest, while in adult life cervico-trochanteric fractures were most frequently encountered. Of 136 cases kept under observation for a minimum period of eight months, 96 were treated by bloodless methods. The results in 14 were bad, in 22 moderate, in 23 good, in 33 excellent, and 4 died. Among 40 treated by operation the results were bad in 9, moderate in 14, good in 11, and excellent in 6.

Therapeutics.

291 Liver Administration in the Anaemias of Childhood.

J P GRIFFITH and J P SCOTT (*Med Journ and Record*, August 1st, 1928, p 121) summarize the conflicting views regarding the administration of inorganic iron in anaemia, and remark that the mode of its assimilation is still unknown. That a low iron content of food is not the only cause of anaemia is shown by the fact that administration of any form of iron relieves some cases, while in others no improvement occurs even when the food is rich in iron. They describe seven cases of anaemia of different type and degree occurring in girls whose ages ranged from 4 months to 6 years. Four of these children were of European descent, and three were negro or mulatto. In only two cases did improvement follow administration of liver, and in one instance other forms of treatment employed vitiated any conclusion in favour of liver administration. In the other case the decided and rapid improvement may have been due to the liver given, but this was not certain. Among the patients who did not improve one received the treatment for a short time only, yet long enough for some improvement to have occurred. The authors do not condemn liver diet in anaemia, but conclude that in the severe anaemias of early life it may fail completely, it is doubtful whether, in the milder cases, especially of the chlorotic type, it presents any advantage over inorganic iron. Where the child's condition permits of the rebuilding of haemoglobin it is probable that administration of iron in any form will do good. Where other factors are present, causing anaemia, it is doubtful whether either liver or iron in any form will be useful. The authors add that too great dependence on liver treatment will lead to disappointment, pernicious anaemia is excepted from this criticism, but this disease rarely occurs in early life.

292 Treatment of Small pox

P TEISSIER (*Bull Méd*, July 25th and 28th, 1928, p 831) describes the treatment of small pox by xylol and convalescent serum. The action of xylol is said to be threefold. It causes the eruption to abort and prevents suppuration, it acts as a deodorant, and it prevents the formation of scars. It has no action in cases in which haemorrhages appear early or in malignant confluent small pox, the rapid course of which does not allow the drug to act, but indirectly it has considerably reduced the gravity and mortality of small pox by preventing suppuration, which is the most serious feature of the disease. In moderate cases xylol is given in wine or milk in doses of 60 drops, which are rapidly reduced to 20 or 10 drops a day. In severe confluent or late forms the dose should be 100 to 120 drops for men, 80 to 100 for women, and 20 to 50 drops for children. Convalescent serum or whole blood is obtained from patients between the twenty-fifth and fortieth days of disease, after excluding the presence of syphilis or tuberculosis in the donor, it is injected subcutaneously, or in severe cases intravenously, in doses ranging from 25 to 100 c.c. The effect of the treatment is a rapid fall of temperature, slowing of the pulse, rise of the blood pressure, and improvement of the general condition.

293 Ammonium Ortho-iodoxy Benzoate in Arthritis.

M SMITH (*New England Journ Med*, July 19th, 1928, p 133) discusses the treatment of arthritis with particular reference to the use of ammonium ortho-iodoxy benzoate. In many cases patients derived no benefit or were made worse, these patients were constipated or complained of gastro-intestinal symptoms, without presenting evidence of other foci of infection. In other cases the removal of such foci had not resulted in relief. Patients who remained unbenefited by this treatment after removal of other foci almost always gave evidence of constipation or some form of gastro-intestinal dysfunction. This led to the impression that the focus of infection lay in the

large bowel, the sluggish action of which favours increased bacterial growth and absorption of toxic products. Smith states that this ammonium preparation is effective when given by the mouth or rectum, but the intravenous route is preferable, the size of the dose is regulated by grouping patients into those above 110 lb in weight and those below. In the case of patients of the lighter weight the initial dose should not exceed 0.3 gram, with subsequent doses up to 0.7 gram. The initial dose for patients over 110 lb in weight should not be more than 0.5 gram and the later doses less than 1.0 gram, each dose after the initial one being increased by 0.2 gram until satisfactory results are obtained. No harm appears to result from repeating the injections at 48-hour intervals, the average number given being from 15 to 20. Other forms of treatment should be used concurrently. Occasionally it was found that acute exacerbations of the arthritic symptoms followed administration owing to an increased absorption of the toxin from the gastrointestinal tract, the possibility of such harmful action in patients not benefited must be considered before repeating the injections.

294 Mercury Lamp Treatment of Whooping cough

J. BECKER (*Munch med Woch*, June 22nd, 1928, p. 1070), as the result of careful observations on his own children, aged 9 and 21 months respectively, concludes that treatment of whooping cough in the paroxysmal stage by irradiation with the mercury lamp had the effect of reducing the number of attacks during the second half of the night. Suggestion could be excluded owing to the age of the children, and Becker is inclined to attribute the good effect of the treatment to diminution of the reflex excitability, by which the nervous element in whooping cough was favourably affected. The irradiation also acted by causing a fall of blood pressure, probably by acting on the calcium metabolism and vegetative nervous system.

Neurology and Psychology.

295 Myasthenia Gravis

A. N. FOXE (*Journ Nerv and Ment Dis*, August, 1928, p. 134) reports a case of myasthenia gravis with visceral symptoms, and contrasts it with one of dystonia musculorum deformans, the ready exhaustion of the somatic musculature in the one and the ceaseless movement in the other being striking, and leading to the deduction of a common origin of the two maladies. It was found that the myasthenic visceral phenomena were functionally the reverse of those reported by Kaufman, Savitsky, and Fried in dystonia musculorum. A clinical contrasting table of the two present cases is given, from which it is seen that the sex, age, etiology, onset, and course in each is the same. The patient with myasthenia was easily fatigued and always sought the position of greatest ease, there was a tendency to hypotension, atonia of the stomach with induced vomiting, constipation due to atonia, vesical relaxation, and apathy. The dystonia patient showed constant movement, with greatest comfort when up and moving, a tendency to hypertonus, retroperistalsis with vomiting constipation due to spasm vesical tenesmus, and excitability. Foxe states that both are diseases of the somatic and visceral musculature, the motor system being essentially affected without involvement of the pyramidal tract. In conclusion, he quotes the pathological findings in the central nervous system in myasthenia reported by several authorities. From the work of Tchiriev, Boeke, Agdnhr, Sherrington, and Hunter on the double innervation of somatic muscle Foxe concludes that it is possible that the two diseases here considered are purely vegetative disturbances, but whether a single central system controls a special phase of tone, or whether there are opposing or balancing centres which determine the exhaustibility and overactivity of muscle, is questionable.

296 Actinomyces of the Central Nervous System

B. O. LEDEBOER (*Nederl Tijdschr v Geneesk*, March 10th, 1928, p. 1202), who records an illustrative case, states that although actinomyces is generally recognized, its localization in the central nervous system is often missed. Ponick, in 1882, was the first to describe two cases of actinomyces of the brain, and Morach in 1922 collected 48 cases of actinomyces of the central nervous system from the literature. He showed that the disease was more frequent in men than in women, and that the ages of the patients ranged from 15 to 70, the highest incidence being at about the age of 30. The persons most frequently affected were farmers and others who came in contact with grain. In most of the cases the central nervous system was affected by spread of the disease from another part of the body, primary involvement of the brain being very rare. The most frequent

form was meningitis. Ledebor's patient was a young man, aged 19, whose first symptoms were ptosis, diplopia, and violent headache, followed by complete right ophthalmoplegia, swelling of the right half of the face, high fever, emaciation, great increase of cells in the cerebro-spinal fluid, Kernig's sign, slight delirium, and the presence of pathological reflexes in the feet. No organisms were found in the blood or cerebro-spinal fluid, either on direct examination or in cultures. Death ensued, and the necropsy showed suppurative meningitis over the base of the temporal lobe, which was adherent to the base of the skull and one large and several small abscesses within the temporal lobe. On microscopical examination numerous actinomycotic organisms were seen. Nothing abnormal was found in the other organs.

297 Hemiplegia with Extensive Naevus and Mental Defect

T. BRUSHFIELD and W. WYATT (*Brit Journ Child Dis*, April-June, 1928, p. 96) refer to their previous papers on this subject (see *Epitome*, August 27th, 1927, para 178, and January 28th, 1928, para 99) and the case since reported by Hugo (ibid., April 21st, 1928, para 396), and describe the following pathological changes found in one of their cases. A naevoid condition of the meninges was found at the base of the brain after death in one case, and in two others the existence of a small meningeal naevus was suggested by x-ray appearances during life. Microscopically the cerebral cortex showed a generalized deficiency of neurons, many of which were immature. The authors conclude that whereas the paralytic features of the cases may be ascribed to the presence of intracranial naevi, the mental defect may be only partly due to this, since there was also a definite underdevelopment of neurons throughout the brain examined.

298 Emotional Factors in Disease

A. LUMIÈRE (*Presse Méd*, August 8th, 1928, p. 993) discusses some of the phenomena in physical and psychological medicine. Beginning with the fact that the blood pressure changes after a shock, he goes on to suggest that the more lasting and profound effects are due to the redistribution of colloids in the body fluids, which lead to a flocculation. This in turn may lead to more colloid changes, and a vicious circle be produced. Thus a psychic stimulus may give rise to persistent derangement of the functions of the sympathetic system. The great polymorphism of the after effects of shock is explained by the abnormal flocculates circulating in organs of different sensitivity. Thus there may occur crises of asthma, epilepsy, psychoses, and dermatoses, following an infection, a trauma, an intoxication, anaphylactic sensitization, or at certain periods of life. The author adds that his theory may explain why post-emotional troubles, persisting even for years may sometimes completely disappear following a colloidal shock. He admits that his explanatory theory is open to discussion, but claims that it has the merit of being in accordance with the facts.

Obstetrics and Gynaecology.

299 Pregnancy Toxaemias of Renal Origin

I. W. KAHN (*Amer Journ Obstet and Gynecol*, August, 1928, p. 201) believes that the kidney is an important etiological factor in the toxaemias of pregnancy, and that it has usually been previously affected in childhood, puberty, or adolescence, or has become secondarily involved from extraneous foci of infection. Prutz found renal involvement in all but seven instances out of 360 necropsies after eclampsia, and Pollack of Vienna noted the same condition in 98 per cent of 139 cases. Kahn divides the toxaemias of pregnancy into early and late, the former including those of pernicious vomiting and the latter the eclampsias. He regards a case as mildly toxemic when there is persistent nausea and vomiting, and states that though in many such patients the urine appears normal, yet a complete investigation will reveal pathological conditions. As the result of a study of 52 cases the following measures are advocated when there is the faintest suspicion of toxemia in early pregnancy. Careful inquiries should be made concerning possible antecedent renal or other urogenital involvement, and there should be a complete analysis of the day and night urine. Other essential steps are the cystoscopic examination of the bladder, the passage of catheters into both ureters and the collection and culture of specimens of urine from each side, renal function tests, and pyelographic investigation. After determining the presence of some renal lesion by these methods Kahn employs the following treatment. A urinary antiseptic is given by the mouth. Full doses of caprokol proved efficacious in many cases but if this was too expensive, teaspoonful doses of

effervescent granules of formohydric given every four hours in a tumbler of water proved an excellent substitute. The ingestion of water, preferably in small quantities at frequent intervals, is encouraged as soon as the vomiting lessens. Some patients benefit from the use of autogenous vaccines, but local measures directed to the kidney itself are the most important. These consist of irrigating the renal pelvis and calyces with 2 per cent boric or saline solution or sterile water. After the lavage 5 to 10 c. cm. of neosalol, mercurchrome, or silver nitrate is instilled into the renal pelvis, the irrigations and instillations are repeated every fourth or fifth day. In eight of the cases the ureteral catheters were left in place for several days until satisfactory drainage was established. As the patient improved, catheterization was performed only once a week, and, when she was free from symptoms, the ureter was finally dilated in order to prevent the formation of an inflammatory stricture and obstruction of the renal pelvis. A coincident cystitis is treated by intravesical irrigations or instillations, strictures and calculi were adequately dealt with. Kahn maintains that in many patients pregnancy can be safely carried to term if a definite renal or ureteral involvement is found and adequately treated.

300 Diagnosis of Submucous Fibromata.

S. VIDAKOVITCH and M. SMOKVINA (*Gynecol. et Obstet.*, June, 1928, p. 553) have employed hystero salpingography in the diagnosis of certain diseases of the internal genitalia. As regards sterility and fibromyomata, they record several successes in the recognition of submucous fibromyomata. While the detection of both subperitoneal and interstitial fibromyomata is usually easy by ordinary clinical examination, when the tumour is sufficiently large the diagnosis of submucous tumours frequently necessitates dilatation of the cervix and digital examination of the uterine cavity, sometimes the sound or the curette is required also. The authors prefer to inject Iliodol, followed by a skidogram, as being a safer and more rapid procedure. They have employed this method in nearly 150 cases without any complication. They recommend that in all cases of motor rhagia in which manual examination shows only slight uterine enlargement skidography should be performed as a routine. In several cases hystero salpingography, after Iliodol injection, has revealed submucous tumours which were not previously suspected. The authors remark that curettage or x-ray treatment of fibromyomata may not only fail to cure, but necrosis and even gangrene of the tumour may follow. From the point of view of treatment accurate diagnosis is necessary, since subperitoneal and interstitial fibromyomata require a different procedure—namely, x-rays or abdominal myomectomy—while the submucous variety should be enucleated, or, if too large for this, vaginal hysterectomy should be performed. Submucous fibromyomata give characteristic skidographic shadows, the normal triangular image being distorted and irregular, large or small shadows appearing. Other lesions, such as blood clot, placental fragments, polyps, and neoplasm, may produce an irregular image; these may be difficult to distinguish, but the image of a fibromyoma is more regular and definite. Further, in fibromyomata there are no uterine contractions, while in other lesions forcible irregular contractions are almost always present. The authors give illustrations of seven typical cases, with drawings of the actual tumours *in situ*.

Pathology.

301 Meningeal Permeability and Physical Changes in the Blood

L. STERN, E. L. ROMEL, and C. A. GUERTCHIKOWA (*C. R. Soc. de Biologie*, July 6th, 1928, p. 363) have tried the effect of altering the H ion concentration of the blood on the permeability of the meninges to certain crystalloids, colloids, and antibodies. To raise the pH sodium carbonate or sodium hydrate solutions were injected, by this means a pH of 8.4 high as 7.72 was obtained in extreme cases. To lower it sodium hydrogen phosphate was injected, or the animal was made to inhale CO₂. In extreme cases the pH fell to 6.61. The animals used were cats and rabbits. The test substances—sodium iodide, sodium ferrocyanide, colloidal trypan blue, and haemolysin—were injected intravenously either at the same time as the injection of the substances designed to alter the H ion concentration or till the pH had returned to normal. About ten to fifteen minutes later a specimen of cerebro spinal fluid was removed by suboccipital puncture, and tests made for the substances that had been injected. The results showed that any disturbance of the H ion concentration of the blood increased the permeability of the meninges to all three

classes of substances, but that increasing the H ion concentration was more effective than lowering it. L. STERN, S. M. ZEITLIN, and R. M. GOZMAN (*ibid.*, p. 365) tried the effect of altering the osmotic pressure of the blood on the permeability of the meninges. To raise the osmotic pressure they injected highly concentrated Ringer's solution or a solution of glucose, to lower it they injected large quantities of water or some other hypotonic solution. The results showed that any marked increase or decrease of the osmotic pressure of the blood—above $\Delta = 0.8$ or below $\Delta = 0.45$ —increased the permeability of the meninges. The first substances to pass through were the haemolysins, then came the crystalloids, and lastly the colloids. The effect lasted for a considerable time after the return of the pressure to normal. From these and other experiments the authors conclude that the alteration in the barrier between the blood and the cerebro spinal fluid is probably determined by an alteration in the anatomical structure of the cells forming the barrier, and that this alteration can be brought about by varying the pH or the osmotic pressure of the blood.

302 The Pathogenicity of *B. abortus* for Man

M. KRISTENSEN (*Centralbl. f. Bakt.*, July 25th, 1928, p. 89), working at Copenhagen, examined the serums of 1,177 patients suspected of suffering from enteric fever for agglutinins to *B. abortus* Bang, no fewer than 89 agglutinated this organism to a titre of 1 in 100 or higher. He then proceeded to make blood cultures in order to isolate the infecting organism. From 2 to 5 c. cm. of blood was placed in fluid media—either glucose citrate asclitic broth, horse serum broth, or liver broth, the cultures were incubated at 37°C. for ten to fourteen days in an atmosphere of 10 per cent CO₂, and subcultures were made at intervals on to asclitic or serum agar. From 13 out of 20 bloods examined in this way an organism was recovered that was indistinguishable from *B. abortus*. It had the usual morphological, cultural, and biochemical reactions of this organism, it was agglutinated to titre by a serum prepared against a cattle strain of *B. abortus*, cross agglutination and cross absorption tests carried out with four human and five cattle strains and their corresponding antisera showed all organisms to be identical, injected into guinea pigs the human strains gave rise to the enlarged spleen and lymphatic glands and the necrotic foci in the liver which are characteristic of *B. abortus* infection, and finally, intravenous injection of two pregnant cows was followed by abortion, and *B. abortus* was demonstrated in the foetus. Though positive blood cultures were obtained in only 13 out of the 20 patients examined, the author thinks that there is little doubt that the other 7 patients, as well as the remaining 69 who were not examined so fully, were suffering from infection with *B. abortus*. The clinical picture was one of undulant fever, accompanied sometimes by severe sweating, neuralgias and arthralgias, swelling of the spleen, and other minor symptoms. Of the 89 cases 58 occurred in men and only 21 in women, no patient was under the age of 13. Clinically they were diagnosed as enteric fever, generalized or latent tuberculosis, malaria, or sepsis. Only one patient died. For treatment the author recommends confinement to bed, a nourishing diet, and, if possible, an antiserum to *B. abortus*.

303. Virus Neutralization in Poliomyelitis

T. W. STEWART and P. HABELBAUER (*Journ. Exper. Med.*, September 1st, 1928, p. 449) note that during the past decade three types of antipoliomyelitic serums have been employed in the treatment of acute anterior poliomyelitis—namely, the serums of convalescent human poliomyelitis, serums from horses immunized against the streptococcal supposid by Rosenow, and others to be the etiological factor in this disease, and the Pettit serum prepared at the Pasteur Institute, which consists of sheep or horse serum from animals supposedly immunized by repeated injections of emulsions of spinal cords of poliomyelitic monkeys. Since the two latter serums have been more or less widely used, the authors have made a further study of their neutralizing action on the virus of poliomyelitis. Monkeys were used as the test animals, and all the experiments were rigorously controlled. These showed that the Rosenow antistreptococcal serum, concentrated or nonconcentrated, does not neutralize the poliomyelitic virus as tested in monkeys. The Pettit horse serum neutralizes it only occasionally, while "immune" sheep serums prepared according to Pettit's method do not neutralize the virus even when the normal serums of the same animals have caused neutralization. The reason for such chance neutralizations is obscure and the authors add that there should be no confusion with the constant action of both human and monkey convalescent serums. The authors conclude that experimental evidence affords no basis for the use of either the Rosenow or the Pettit serum in the treatment of poliomyelitis.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

304 Hypertensive Mitral Endocarditis.

IN a series of forty cases of chronic mitral endocarditis A DUMAS (*Presse Méd.*, September 15th, 1928, p 1172) was surprised to find at the necropsies that nine of these were accompanied by arterial hypertension. Other authorities have noted the association of these two conditions and in 1926 Boas and Linborg stated that the frequency of arterial hypertension in the course of mitral stenosis, especially after the age of 40, was too great to be considered accidental. As a result of his present study Dumas maintains that chronic endocarditis involving the mitral valve can be accompanied by arterial hypertension in old patients who have tolerated these lesions well. The same phenomenon occurs in aortic insufficiency, with which the author does not deal, as it is a better recognized condition. This hypertensive form of mitral disease is characterized by a small systolic or post systolic souffle of mitral insufficiency. The nine cases noted could be divided into two groups—those in which death resulted from a progressive cachexia with tonsillar hypertrophy, as occurs in arterial hypertension without mitral involvement and those less important, in which death was caused by left ventricular insufficiency. The anatomical lesions were always clear, they usually consisted in a calcitrated capping of the mitral valves, and sometimes in a slight atheromatous induration with a calcified nucleus. In only two cases was there a particularly marked stenosis. Arterial hypertension may mask the usual signs of mitral disease, and, besides the already mentioned souffle, only a hard mitral sound and a presystolic bruit (liable to be confused with the gallop bruit) may be heard. Many cases of mitral disease can remain completely latent and be mistaken merely for hypertension. It is advised, therefore, that in all cases of the latter disease a most careful auscultation should be made to reveal the presence or absence of mitral involvement. Dumas believes that subacute endocardial inflammation is the cause of this hypertensive condition, as in all of the cases no renal lesions were found to account for it.

305 Uræmic Paralysis following Scarlet Fever

Y. SHAW (*Brit Journ Child Dis*, July–September, 1928, p 191), who records a personal case, illustrates the rarity of cerebral palsies in scarlet fever by the fact that Rolleston in 1927 had been able to collect only 75 cases, 4 of which he had seen himself. Shaw's patient was a boy, aged 8, who developed nephritis on the twenty eighth day of a mild attack of scarlet fever. About a fortnight later generalized convulsions occurred, which were successfully treated by venesection and lumbar puncture. Left homiplegia, however, was found on examination the next day, and persisted, although the renal condition cleared up. An exceptional feature of the case was the permanent character of the palsy, uræmic paralysis as a rule being transitory.

306. Nephrosis in Children

GLADYS L. BOYD (*Canadian Med Assoc Journ*, July, 1928, p 46) prefates her description of some cases of nephrosis by reviewing the origin and significance of this term. The clinical association of marked oedema and intense albuminuria, in the absence of nitrogen retention, hyperplasia, or gross hæmaturia, has been known for rather more than twenty years, and the balance of evidence has suggested a general toxæmic origin for the renal changes. In favour of this view are the frequent presence of degenerative lesions in other organs and the nasal appearance of anæmia and vague ill health some time before the oedema is noticed. Although no acute illness is typically associated with nephrosis, attacks of bronchitis and gastro-intestinal upsets not uncommonly precede the hydraemia. Of a series of children suffering from nephrosis 95 per cent were found to have had measles, and tuberculosis also seemed to be a frequently related condition. While pyuria was often present the urine was generally sterile, *B. coli* being found in the infected cases. Some observers have regarded staphylococci as an important etiological factor, with *Staphylococcus albus* and *aureus* as the predominating organisms. Four cases of nephrosis in children were studied by the author in the hope that in them as contrasted with adults, renal pathology might correspond more closely to clinical findings. Increase in size of the kidney and preponderance of tubular changes were constant observations. Where in later cases, glomerular changes also were found, it was difficult to determine whether these were primarily inflammatory or secondary

to cellular degeneration. Fatty infiltration of the liver was found always, similar changes being discovered frequently in the heart.

307

Common Cardiac Problems

M. D. SILVERBERG (*Med Journ of Australia*, June 23rd, 1928, p 764) reviews the clinical and therapeutic problems presented by syncope attacks, cardiac neuroses, and precordial pain. He classifies syncope into harmless and serious varieties, the former being dependent upon disturbances of the nervous mechanism, which may consist in overaction of the vagus and inhibition of the heart or in vasomotor pooling in the splanchnic area, or in a depressor vagal mechanism induced by a sudden rise of pressure in the aorta. Grave forms of syncope are commonly the result of pathological changes in the myocardium, and are usually recognizable by cardiac irregularities, Stokes Adams attacks belong to this group. Recurring unduly loud first sounds produced by aortic reinforcement and arrhythmic systolic sounds in the long pauses are of diagnostic value in heart block. Passing to cardiac neuroses, known also as effort syndrome and irritable heart, the author emphasizes the importance of allaying the patient's anxiety, actinosis and of recognizing the chronic toxic condition so frequently present. The identity of these cases with those of hypothyroidism and thyrotoxicosis is regarded as more apparent than real. Treatment with bromides, glycerophosphates, and calcium salts is recommended. In considering precordial pain the author follows Mackenzie's scheme of primary and secondary angina, the latter including the harmless forms common in young women and in neurotic subjects generally, the pain being usually unrelated to exertion, and not substernal or radiating, the patient is restless as compared with the immobility characteristic of primary angina. The well defined group of coronary thrombosis is described, and stress is laid upon the risk of mistaking mild attacks of cardiac pain for indigestion when, as often happens, the discomfort comes on after meals. In severe attacks the pain centred in the epigastrium, the vomiting, and signs of collapse may suggest an abdominal catastrophe, while pyrexia and leucocytosis may enhance the similarity.

Surgery.

308.

Splenectomy for Trauma.

J. T. CONNORS (*Annals of Surgery*, September, 1928, p 388) reports conclusions drawn from 32 cases of splenic injury, motor accidents accounted for 18 of the cases, and 22 occurred in persons under the age of 21. He attributes the fact that 25 cases occurred in males and only 7 in females to the greater occupational and industrial hazards to which men are exposed. In all cases but one the spleen was normal, except for the traumatic lesion, in the one exception a spleno-medullary leukaemia was found. The traumatic lesion usually consisted of a laceration which divided the spleen into two parts, in some cases the laceration was stellate. In all cases the abdomen was filled with blood and blood clots, the latter being chiefly round the spleen and on the left side of the abdominal cavity while free blood was found in the pelvis. Of the 32 cases, only 15 patients survived, in each case as the result of operation, 7 cases which were not operated on terminated fatally. In many instances there were injuries in addition to that of the spleen. The symptoms were chiefly those of shock and hæmorrhage, with abdominal pain, often localized in the left hypochondrium. Vomiting occurred in 7 cases, dullness on percussion in the left flank in 16 cases, obliterated liver dullness in 3 cases, and abdominal distension was invariably present. Connors adds that the treatment should be immediate operation in all cases of splenic rupture, splenectomy is the operation of choice, its operative mortality being 40 per cent. A subsequent blood transfusion is of great value. It was found that a slight anaemia, which lasted for several years associated with a slight leucocytosis, followed operation, but otherwise the health of persons whose spleens had been removed for trauma was not adversely affected.

309

Cerebral Gas Gangrene

W. SCHÄR (*Deut Zeit f Chir*, September, 1928, p 414), who records an illustrative case, remarks that gas gangrene in time of peace is a rare occurrence. In the great majority of cases the extremities are involved and the trunk is rarely affected. The condition chiefly develops in the muscles. In

recent years other localizations have been described, such as in the lungs, liver, gall bladder, and in the peritoneum after appendicectomy. Schür now reports a fatal case of cerebral gangrene in a boy, aged 14, following an injury to the left eye. Death occurred three days after the accident, with symptoms of meningitis and abscess in the frontal lobe. The necropsy showed recent basal meningitis and an abscess partly filled with gas in the base of the left frontal lobe. Bacterial examination revealed a hitherto unknown bacillus which formed gas in both aerobic and anaerobic media, and killed a guinea pig in eight hours with the typical signs of gas gangrene. Only five cases of cerebral gas gangrene have hitherto been described, in four patients, two of whom recovered. It was the result of war wounds and due to Fränkel's bacillus. In one patient it followed otitis media, and was due to a Gram negative non mobile anaerobic bacillus. Cerebral gas gangrene has no characteristic symptoms, but presents the picture of an ordinary cerebral abscess, or, most frequently, of a rapidly progressive meningitis, as in Schür's case. Treatment consists in free evacuation of the abscess and early and intensive anti gas gangrene serum therapy.

310. Intestinal Tuberculosis causing Obstruction

J R B BRANCH (*Arch of Surgery*, September, 1928, p 440) believes that in the most severe cases of pulmonary tuberculosis there is some intestinal involvement, lesions being found in the intestinal tract of 70 to 90 per cent of patients dying of this disease. The condition is usually ulcerative, stenosis or stricture developing in only 25 per cent of cases. This type of lesion is progressive and associated with processes in the lungs, and is called "secondary," the "primary" type being hyperplastic. In about 85 per cent of cases the involvement in intestinal tuberculosis is in the terminal ileum, caecum, and proximal colon, in some cases the appendix also is involved. In all cases there is a generalized thickening of the entire wall of the bowel with old healed scar tissue, resulting in stenosis of the lumen. In diagnosis there may be confusion with appendicitis or malignant growth but as most cases occurred in young people between 25 and 30 years of age malignancy was improbable, and a ray examination confirmed the clinical diagnosis of intestinal tuberculosis. Treatment involves resection of the diseased portion of the bowel, with enterostomy, two features in the operative and post operative procedure being important: (1) the prophylactic or complementary enterostomy suggested by Mayo to avoid paralytic ileus, and (2) the limiting for four or five days after operation of all fluid intake to the subcutaneous and intravenous administration of solutions of physiological sodium chloride or dextrose. Nothing must be given by the mouth or the rectum, morphine may be used liberally to reduce peristalsis to a minimum.

311 Treatment of Empyema following Pneumonia

H BINNEY (*New England Journ Med*, August 30th, 1928, p 410) describes the principles underlying the modern treatment of empyema. Realization of the fact that the mediastinum is not necessarily a rigid partition, and that pressure changes in one pleural cavity may therefore be transmitted to the other, has led to the avoidance of open drainage and its attendant pneumothorax, especially when pneumonia is present and the vital capacity low, and if there has been no time for stabilization of the mediastinum by adhesions. The author has tried preliminary aspiration of 200 to 300 cc of pus in 28 cases, in 17 the condition was thereby improved prior to operation. The indications for this procedure are underlying pneumonia, cyanosis and dyspnoea due to pneumonia or much fluid, or unduly rapid pulse. If the pus is found to be too thick to pass through a needle, trocar puncture and catheter drainage is advised. With regard to diagnosis, the atypical forms give rise to greatest difficulty—for example, the encapsulated, interlobar, apical, or mediastinal empyema. For the detection of these abnormalities careful physical and x ray examination is essential and subsequent wide exploration at operation. As a routine method the pus is gradually drained off through a catheter introduced into the thorax by means of a trocar and cannula, and since the substitution of this method for the old open drainage at the Boston City Hospital the mortality from this condition has been halved. In accordance with other observers, the author has found that in pneumococcal empyema the chance of recovery is twice as great as in streptococcal empyema. The occurrence of chronic empyema depends upon various factors, such as age, organism, and complications, but it is believed that about 20 per cent of cases become chronic when treated by open drainage, the perfection of closed drainage methods has seemed up to the present to reduce greatly the incidence of chronic empyema, this condition being developed in only 4.7 per cent of the author's 126 cases treated by closed drainage.

Therapeutics.

312

Bismuth as a Diuretic.

H G MEHRTENS, P J HANZLIK, D C MARSHALL, and N S BROWN (*Journ Amer Med Assoc*, July 28th, 1928, p 223), as the result of tests with a constant fluid intake, confirm their original impression, derived from an uncontrolled fluid intake that bismuth administered intramuscularly acts as a diuretic in both ambulatory and confined cases. Single and repeated doses of bismuth metal suspended in dextrose solution, or of potassium bismuth tartrate, or bismuth salicylate suspended in oil were used. On an uncontrolled fluid intake it was found that the urine output increased simultaneously with the excreted bismuth in the urine, the optimum diuresis coinciding with the peak of bismuth excretion and generally diminishing as the excretion of bismuth decreased. That the diuresis is due to the bismuth ion is shown by the fact that similar results were obtained with either the metal or the tartrate and salicylate compounds, the ions of the latter being insufficient in quantity to cause diuresis. Large or repeated doses were more effective than small or single ones, but it was found that the bismuth preparations caused considerable increase in urine output, ranging from 31 to 150 per cent above that prior to medication. With a constant water intake similar results followed intramuscular injection, and even single doses produced a definite increase in output. The effects were temporary and lasted about a day, but when the urine output had returned to its previous level reinjection of the bismuth produced an increase, it was found that three doses spaced a day apart gave the best diuresis. With the ordinary dosage used in the treatment of syphilis such diuresis did not cause any demonstrable injury to renal function. With the oral administration of from 3 to 5 grams of the subnitrate an increase sometimes occurred, but was not dependable since only five patients were tested a more extended trial is desirable. Bismuth subcarbonate was found to be ineffective in producing diuresis. Any such resulting diuresis would appear to be due rather to the nitrite action, since there was no accompanying bismuth excretion, and moderate nitrite effects on the circulation occurred. No toxic effects followed any of the preparations or methods of administration, and the authors conclude that their results justify the intramuscular use of bismuth in the treatment of clinical oedemas.

313 Treatment of Early Cerebro-spinal Syphilis

A POSITIVE Wassermann or gold sol reaction in the cerebrospinal fluid is considered by F BERING (*Wien Klin Woch*, July 12th, 1928, p 977) an indication for malaria treatment. He adds that no thorough antisyphilitic treatment is possible without an examination of the cerebrospinal fluid. Not much significance can be attached to a positive or negative reaction in the fluid in the secondary stage, therefore the examination should be made at the end of the treatment or during the stage of late latency, when a positive reaction is of primary importance, implying that the central nervous system is threatened by the syphilitic virus. Bering remarks that it is not certain that commencing involvement of the central nervous system can always be detected in the cerebrospinal fluid. The examination of the blood only is certainly insufficient, since very pronounced changes may be present in the cerebrospinal fluid, while the reaction of the blood remains negative. In the presence of a positive reaction in the cerebrospinal fluid the routine antisyphilitic treatment is insufficient, and malaria treatment is indicated. Eight attacks of malaria are usually sufficient, but the malaria treatment should in all cases be followed by an intensive salvarsan or bismuth treatment. The malaria treatment has proved useful also in cases where, in spite of intense antisyphilitic treatment, the reaction of the blood remained positive. Bering considers that the results of malaria treatment in tabes have been variable, they were occasionally good, but sometimes there was no response. No permanent harm has been caused to any patient by the malaria inoculation. No case of syphilis treated prophylactically with malaria developed general paralysis or syphilis of the central nervous system.

314.

Arsenio in Lambliæ Infestation

A H A MARTENS and C H KOERS (*Nederl Tijdschr v Geneesl*, August 4th, 1928, p 3781), who record an illustrative case in a woman aged 25, state that the connexion between intestinal symptoms and the presence of a large quantity of flagellate parasites in the intestine cannot be denied. It is an open question, however, whether the parasites play a primary or a secondary part in the production of the clinical picture, although it is probable that pre-existing intestinal disturbance forms a suitable soil for their development. According to the authors it is improbable that the parasite multiply on the mucous membrane of theiliary tract.

Treatment at present is unsatisfactory, the ordinary lutes that disinfectants cannot destroy the parasites. Investigations on the effect of arsenco in the form of neosalvarsan or stovarsol yielded the following results. After the intravenous injection of neosalvarsan arsenco could be found one and a half hours later in the duodenal fluid and the parasites were still active, twenty minutes later the arsenco reaction in the duodenum was strongly positive and the flagellates were motionless. Three days later the arsenco reaction was feebly positive and there were no parasites. In another ten days the arsenco reaction was negative and mobile flagellates were found. Arsenical treatment therefore, has a favourable effect but only of a temporary character, it must be continued for a long period and in fractional doses. Stovarsol appears to be a suitable drug for this purpose, but the authors state that they have not hitherto had a permanent success after six months' treatment with this drug.

Ophthalmology.

315

Syphilis of the Orbit.

G. F. ROCHAT (*Nederl. Tydschr. v. Geneesk.*, May 19th, 1928, p. 2438) states that in the presence of symptoms suggesting a tumour in the orbit there is always a small chance of sparing the patient a serious and disfiguring operation by careful inquiry as to the possibility of syphilitic infection. Violent nystagmus, especially at night, from the onset of the illness and the paralysis of several ocular nerves associated with only slight ophthalmos, are suggestive of gumma of the orbit. He adds that it is always worth while to try the effect of antisyphilitic treatment, even when the presence of lues cannot be proved. A woman, aged 79, who had contracted syphilis in early life, developed slight ophthalmos and ocular palsies. There was doubt as to whether the condition was due to a gumma or to tumour, as the Wassermann reaction was negative. Potassium iodide had no effect, and the ophthalmos and paralysis increased, so that evacuation of the orbit had to be considered. Mercury and salvarsan were first tried, and complete recovery followed in a few weeks. Numerous cases have also been recorded in which non-syphilitic processes in the orbit suggestive of tumour were cured by mercury and potassium iodide.

316 Tendon Transplantation for Paralysis of the External Rectus

T. H. RODIN and W. F. SWETT (*Amer. Journ. Ophthalmol.*, May, 1928, p. 369) report a case in which this operation was performed with success. Their patient was a man of 61 who had paralysis of the left external rectus resulting from an injury. Under local anaesthesia a curved incision was made through the conjunctiva over the superior external and inferior recti muscles of the left eye, and the tendons of these muscles were exposed. The superior and inferior recti muscles were then split and the lateral halves, so produced, sutured to the insertion of the external rectus. After healing there was still some convergence of the eye, but it could be abducted as far as half way between the primary position and extreme abduction. A few weeks later a complete tenotomy of the left internal rectus was performed, with the result that the eye became straight with apparently full movement in all directions.

317

Angor Ocularis

AMONG the ocular symptoms due exclusively to angiospasm which cause transient or lasting changes, E. AUBARET and J. SÉDAN (*Presse Méd.* September 8th, 1928, p. 1139) discuss an autonomous clinical syndrome to which they have given the name "angor ocularis" or ocular anguish. Regarding retinal angiospasm, the theory that the vasomotor nerves have no action on the retinal vessels is disproved by the presence of special branched cells (the cells of Rouget) in the tunica of the retinal capillaries which can modify their walls and therefore their lumen, and also, as has been demonstrated by modern workers, by the presence in the vascular trunks from which all the retinal vessels rise, of a vasomotor mechanism controlled by autonomous centres of sympathetic origin and in relation with the cervical sympathetic and endocrine organs. Ricker has stated that vascular spasms respond to two modes of origin: either a direct one where the cause is found at the point of contraction of the vessel, or an indirect one where the cause lies at some distant point. Angor ocularis is characterized by a constant fear of imminent blindness and the principal symptom is the sudden appearance of a more or less opaque mist, which, though rarely total, suffices to impair vision. Its duration varies from some minutes to a few hours. Frontal or orbital headache is rarely present, this fact, together with its unilateral

position and the incomplete blindness, distinguish this form from angiospasm of cortical origin. Abadie has shown that angiospasm is a factor in causing lesions of the optic nerve, and the present authors incline to the hypothesis that repeated attacks of angor ocularis lead sooner or later to definite retinal lesions. This syndrome is observed in many diseases, including chronic glaucoma, angina pectoris, Raynaud's disease, epilepsy, and hypertension, and in certain intoxications, such as with lead, quinine, tobacco, and alcohol. The authors draw attention to the analogy between angina pectoris and angor ocularis, and the similarity of the latter to certain epileptic auras. At the onset of an attack antispasmodic treatment, especially with inhalations of amyl nitrite, is indicated. Other less active antispasmodics are sodium nitrate, trinitrine, valerian, boron, and morphine. Instillations of atropine are employed locally, and subcutaneous injections of pilocarpine nitrate are useful in that they cause a general vaso-dilatation. Frequently repeated retrobulbar injections of atropine have been recommended by Abadie and have proved beneficial, gonalal is often a useful addition. The periorbital operations of Leriche may cause immediate improvement. Treatment of all intoxications and specific treatment in cases of syphilis should be instituted at once.

Obstetrics and Gynaecology.

318 Thymus and Pituitary Extracts in the Early Stages of Labour

ACCORDING to A. G. LAURITZEN (*Ugeskrift for Læger*, July 5th, 1928, p. 635), Tomesbury of Broslau reported in 1926 that he had made a mixture of an extract of the thymus and of the posterior lobe of the pituitary body, and had used it in 70 maternity cases. It is claimed that the action of this preparation did not change after keeping for a year and a half. After giving clinical details of some of his cases, Lauritzen summarizes them as follows. In abortions good effects were obtained in one case, no effects in two others. Before term, one case was treated with no effects. During the first stage of labour twelve patients were treated with good effects, and one with bad effects. During the second stage of labour seven cases were treated with good effects, two with no effects, and one with asphyxia. During the period of the expulsion of the placenta the mixture was given in one case with good effects, and in another with bad effects. The author notes that these results coincide approximately with those claimed by other writers, and he concludes that his preparation "thymophysin" has a specific action in the first stage of labour, and that it therefore fulfils a long felt want. It provokes stronger and more frequent pulsations of a physiological type, its employment is not followed by secondary atony while the placenta is being expelled, in no case could it be held responsible for asphyxia of the infant, and its chief use is during the first stage of labour. Towards the end of labour its action does not exceed that of pituitrin. The indications for its employment are primary uterine inertia, rigidity of the soft structures, premature rupture of the membranes, and, last but not least, the wish to shorten labour. Contra-indications are marked mechanical obstacles, abnormal presentations, malformations, a contraction ring, infections, and diseases of the heart and kidneys.

319

Hydatidiform Mole.

REEB (*La Gynéc.*, April, 1928, p. 204) records two cases of hydatidiform mole to illustrate marked differences in the clinical evolution. A multipara, aged 53, whose seventh and last child had been born when she was 49 years old, had amenorrhoea for four months. The breasts were enlarged, they contained colostrum and there was marked pigmentation of the areola. The vulva and vagina were slightly cyanosed, the cervix was long and hard, and the external os was slightly permeable. The uterus was enlarged to the size of the head of a newborn child, it was mobile, rather soft, and contained a fibroma as large as a small hen's egg. The appendages were normal. The diagnosis of pregnancy at the fourth month with a small fibroma was made. A month later the patient had not increased in size, she had not felt quickening and had "menstruated" twice. Examination showed that the uterus had not enlarged since the last examination, it felt hard, the bigness of the vagina had not increased, and the breasts had become flaccid. Four months later, on account of pains and the passage of clots, together with the presence of a fibroma, subtotal hysterectomy was performed. The patient recovered. Examination of the uterus showed a fibroma the size of a small apple and a hydatidiform mole. Histological examination revealed that the growth, although it had been retained for five months in the uterus without producing symptoms and without invading the uterine wall, possessed the characters of a hydatidiform mole in active

evolution. In the second case a multipara, aged 42, complained of loss of blood of fifteen days' duration following three months' amenorrhoea. The uterus was enlarged and reached to one fingerbreadth above the umbilicus, it was soft and flaccid, the cervix being very short and the os permeable to the finger. Next day a very large hydatidiform mole was spontaneously expelled, with severe haemorrhage, necessitating swabbing and tamponage. The patient recovered and was recommended to return after four weeks, or before then if she commenced to bleed. This she neglected to do, but eight weeks later presented herself in a condition of severe anaemia following serious haemorrhage. The uterus was enlarged to the size of a two months' pregnancy, it was hard and in mobile anteversion, the external orifice being scarcely permeable. In the posterior vaginal wall was an ulcerated tumour surrounded by clots and still bloodclot, and close to it were several small nodules which were felt as thickening in the recto vaginal septum. The uterus was enucleated and mucosa only removed. One of the vaginal nodules was excised and proved to be a chorion epithelioma. Owing to the patient's anaemic condition, it was only after eight days, when some amelioration had occurred, that it was possible to excise the vaginal growths and to remove the uterus and appendages. The patient died of post-operative ileus on the sixth day. The necropsy revealed one small metastasis on the pelvic peritoneum, there were none in the lungs. The excised nodule from the recto vaginal septum was a characteristic chorion epithelioma, but the mucous membrane of the uterus was perfectly smooth, and no sign of chorion epithelioma could be detected in the uterus. The problem remains unsolved whether in this case the chorion epithelioma in the vaginal wall was primary, or whether it was secondary to a chorion epithelioma in the uterus which had spontaneously cleared up.

320

The Decidua and Lactation.

F. SPIRITO (*Ann di Ostet e Ginecol*, July, 1928, p 755) regards the hypertrophy of the breast during pregnancy and its secretion during lactation as brought about by a combination of hormonal influences, of which one—namely, that of the decidua—is not present until after conception. Animal experiments with placental extracts have led to different results in different hands, this is perhaps explicable by Cora's finding that mammary tissue is not affected by extracts of placenta from which the maternal (decidual) portion has been completely excluded. Among the results reported after repeated injections of decidual extracts are adiposity, regression of the internal genitalia, hyperplasia of the suprarenals, increase in size of the breasts, and secretion of milk. There is some evidence of an increased tendency to abortion in animals after the injections. Spirito reports the results of intramuscular injections into human subjects of an extract of animal placentae made by trituration with glycerin, no unpleasant symptoms were noted and all pregnant patients went on to term. The results in cases of deficient lactation in the puerperium were encouraging, those in a second series of cases, in which patients whose lactation after the antecedent childbirth had been defective received injections throughout the last forty to fifty days of pregnancy, were much better. In a certain number of cases in both series the injections were without effect. Using Spirito's extract in virgin animals, Tesano has induced hypertrophy and lactation in the breasts. Di Nanno, by giving the extracts hypodermically or by the mouth to newborn animals, has found that males show increased growth and females diminished growth—effects which are ascribed respectively to hormonal stimulation of suprarenal and inhibition of ovarian endocrine activity.

Pathology.

321

Etiology of Cancer

G. VILLATA (*Il Politecnico, Sez. Prat*, July 9th, 1928, p 1298) reports four cases under the care of Professor Bobbio in Turin to indicate the importance of the chronic irritative factor in the production of malignant tumours. The irritation may be physical, chemical or thermal, it is often multiple, and is especially liable to occur in a cicatrix. Villata points out that while endeavours to produce new growth by inoculation or by implantation mostly fail, they are more likely to be successful when accompanied by a method which provokes chronic non specific irritation. Malignant tumours may follow exposure to x rays, the application of tar, and infection by the *Cisticercus fasciolaris*, the larvae of taenia, or by demodex. Menetrier stated that Fibiger had again shown the relation of chronic inflammatory phenomena with hyperplasia of tissues and malignant new formations.

77SD

Villata's four cases are as follows: (1) A man, aged 67, was operated upon for a calculus in the bile duct in August, 1924. The liver was enlarged and the gall bladder was inflamed, adherent, and full of calculi. Cholecystectomy was performed, and the patient was discharged cured at the end of September. He was readmitted in September, 1927 with pain in the right lumbar region, and was found to be suffering from diffuse and extensive carcinoma proceeding from the zone previously occupied by the gall bladder. (2) A woman, aged 58, was admitted in January, 1925, with symptoms of gastric ulcer. Extensive and tough adhesions were found between the stomach and the abdominal wall, the ulcer, which was about perforated, was cauterized and folded in after the manner of Balfour. The patient returned in September, 1927, and was found to have a large ulcerating cancer of the stomach in the pyloric region. (3) A woman, aged 45, had had lupus of the face when 25, this responded well to treatments and irradiations. In January, 1927, she showed extensive epithelioma affecting the old cicatrices, the growth being of the spino-collular variety. (4) A woman, aged 41, had a cancerous growth in the right breast which was caused by chronic irritation, she was accustomed to thrust her right breast against the loom in the process of weaving, and a carcinoma developed at the point of recurrent impact.

322.

Bacillus botulinus in Scottish Soils.

G. LEIGHTON and J. B. BUXTON (*Journal of Hygiene*, August 8th, 1928, p 79) report the results of the examination of 100 samples of soil taken from different Scottish counties with a view to determining the presence of *B. botulinus*. The series yielded only 4 per cent of positive results, as compared with 5.5 per cent in Denmark, 7.8 per cent in England, 20 per cent in Holland, and 23.5 per cent in Switzerland. The authors remark, however, that it would not be safe to conclude that the organism is relatively and proportionately rare in Scotland, what is definitely shown for the first time is that both the A and B types of *B. botulinus* occur in Scottish soil. Only eight samples of soil gave filtrates containing tetanus toxin, four of these came from manured cultivated land—one from old pasture and one from moorland. Two soils yielded the A type of *B. botulinus*, this being the first time that it has been found in a European soil. The authors mention that the investigation owes its inception in part to the Loch Maree tragedy in 1922, particulars of which were given in the *Journal* of February 17th, 1923 (p 279), by T. K. Menro and W. W. N. Knox.

323. Fate of Tubercle Bacilli in Various Organs.

M. B. LURIE (*Journal Exper. Med.*, August, 1928, p 155) has made a quantitative study of the rate of growth of human and bovine tubercle bacilli in different organs. The general technique was to inoculate a series of rabbits intravenously with a given dose of bacilli, to kill one or more at varying intervals of time, and to make a rough estimate of the number of living organisms in the different tissues by inoculating Dorset's and Petroff's egg media with diluted suspensions. By this means it was found possible to count the colonies that developed and so obtain an idea of the number of bacilli present in the tissue. In rabbits killed two days after inoculation the number of organisms was greatest in the spleen, next to which came the liver, lung, bone marrow and kidney, in this order. After 0.1 mg of human bacilli the organisms grew most rapidly in the spleen and lungs, reaching a maximum in the spleen after two weeks, and in the lungs after four weeks. In the liver, bone marrow, and kidney the multiplication was very much less, then destruction set in, so that after two months the numbers were greatly decreased. After a similar dose of bovine bacilli multiplication occurred more slowly, and whereas destruction was present in the spleen, liver, and bone marrow after a preliminary period of growth, in the lungs and kidneys the organisms continued to multiply indefinitely. When a smaller dose of bacilli was used (0.001 mg) the same sequence of events appeared, but at a slower rate—that is to say the rate of multiplication and the onset of destruction occurred at a later date. Even six months after the inoculation of human bacilli considerable numbers were still present in the lungs and spleen. The author finds that the growth of the human is faster than that of the bovine bacillus in the rabbit, on the other hand, the human type is destroyed earlier and more completely than the bovine type. With both types destruction occurs first in the liver, spleen, and bone marrow, in the lung and kidney the destruction of the human type is later, while in these organs multiplication of the bovine type continues till the death of the animal. With both types destruction in a given time is more complete in some organs after a large than after a small dose. For these reasons the author concludes that the virulence of a given strain is inversely proportional to its rate of growth in the animal body.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

324 Diagnosis of Lobar Pneumonia in Children

ACCORDING TO A C BELMONTE (*Nederl Tijdschr v Geneesk*, September 22nd, 1928, p 4662), whose paper is based on the study of 66 cases of lobar pneumonia of the upper lobe and 61 of the lower lobe admitted to the Emma Children's Hospital at Amsterdam in the period 1909-27, many cases of supposed appendicitis in children turn out to be lobar pneumonia of the lower lobe. The symptoms suggestive of acute abdominal disease, especially appendicitis, in lobar pneumonia of the lower lobe are the association of abdominal pain, nausea, vomiting, muscular rigidity, and the constant presence of constipation. The symptoms are more likely to be due to a reflex cause than to inflammation of the diaphragm. Whorled abdominal pain was present in only 3 per cent of the 66 cases of pneumonia of the upper lobe, it was found in 40 per cent of the 61 cases of pneumonia of the lower lobe. On the other hand, diarrhoea was present in 66 per cent of the cases of pneumonia of the upper lobe but was found in only 2 per cent of the cases of pneumonia of the lower lobe. The presence, therefore, of diarrhoea in a doubtful case of the kind is much in favour of acute appendicitis.

325 Tuberculosis and Orthostatic Albuminuria.

J VALDES LAMBEA (*La med Ibera*, September 15th, 1928, p 229) asserts that the so-called orthostatic albuminuria is principally met with in young members of tuberculous families who are themselves subject to inactive tuberculosis. These persons have a long narrow thorax with small respiratory capacity. The blood pressure is usually below normal, the stomach is atonic, and there is generally more or less tachycardia. Such individuals, therefore, are examples of Stillor's asthenic habitus, which, according to Lambea, is almost always of tuberculous origin. Of 133 boys aged from 13 to 15, 125 had a family history of tuberculosis, 98 presented Stillor's asthenic habitus and showed signs of active pulmonary tuberculosis on auscultation or radiology, and had a blood pressure below 100 mm of mercury sometimes as low as 91/75. Albuminuria was present in 83 of the 133, and 65 of the 83 were of the asthenic type. Lambea concludes that non nephritic albuminuria in young persons of the asthenic type is due in most cases to tuberculosis and that orthostatic albuminuria is frequently of tuberculous origin.

326 Peripheral Arterio-sclerosis

C LUNDSGAARD and E RUD (*Ugeskrift for Læger*, July 26th, 1928, p 715) have studied at the Rigshospital in Copenhagen the condition of the arteries of the arms and legs as shown by an x-ray examination. The object of this investigation was to ascertain whether skilgraphically demonstrable arterio-sclerotic changes in the peripheral arteries could or could not be correlated with the clinical picture of certain diseases, such as chronic nephritis and angina pectoris. During three and a half years 193 men and 152 women were thus examined, preference in the selection of the patients for this examination being given to those whose clinical symptoms suggested arterio-sclerotic changes, high blood pressure, chronic nephritis, nephro-sclerosis, angina pectoris, coronary sclerosis, myocardial degeneration, diseases of the aorta, or apoplexy. Skiagrams were taken not only of the right forearm and the right foot, but also of the heart. The blood pressure was measured frequently, and the radial and temporal arteries were examined clinically for rigidity, tortuosity, and unevenness. An ophthalmoscopic examination of the vessels of the retina was made in 151 cases. A great difference was found in the distribution of skilgraphically demonstrable peripheral arterio-sclerosis in men and women, 100 of the 193 men and only 13 of the 152 women showing such a change. In no patient under the age of 40 could such peripheral arterio-sclerosis be demonstrated. Between the ages of 50 and 59 there were 82 men and 71 women, and the respective incidence of peripheral arterio-sclerosis was 57 per cent and 55 per cent. Among the 113 men and women with skilgraphically demonstrable peripheral arterio-sclerosis there were as many as 47 whose radial and temporal arteries seemed perfectly normal on clinical examination. Of the 58 patients with skilgraphically demonstrable peripheral arterio-sclerosis whose retinal vessels were examined, only 4 showed arterio-sclerosis of these vessels. Among the 12 men between the ages of 40 and 49 in whom peripheral arterio-sclerosis was demonstrated skilgraphically, as many as 9 suffered from diseases of the myocardium.

Among 44 of the men and 10 of the women the systolic blood pressure was found to be above 150. In other words, the blood pressure was above normal in about 50 per cent of the patients with skilgraphically demonstrable peripheral arterio-sclerosis. Among the 113 patients with skilgraphically demonstrable peripheral arterio-sclerosis there were 25 showing no cardiac symptoms. There remained 88 with cardiac symptoms and 63 with cardiac signs of disease.

327 The Anaemia Infection of Edelmann

M SCHUR (*Wien klin Woch*, August 9th, 1928, p 1153) describes a case of severe progressive anaemia in a boy aged 13. The temperature was 100.4° F, and the skin was puffy and pasty, the heart was not enlarged, but short systolic bruits were heard at all the valvular orifices. The spleen was enlarged, hard, and palpable. The haemoglobin percentage was 37, the red cells numbered 3,420,000, and the leucocytes 13,800, with an eosinophil percentage of 65. There was excessive anisocytosis, blood culture was sterile, and the Wassermann and tuberculin tests were negative. There was no evidence of endocarditis lenta. Five months later the anaemia was more severe, and eosinophilia had risen to 12 per cent. The symptoms suggested Edelmann's "infectious anaemia." Stained blood films showed erythrocytes containing dark blue or violet stained bodies with coronated edges, extracellular rosettes or mulberry like masses of blue stained bodies with reddish centres, and smaller circular reddish violet bodies lying within the red corpuscles. Schur considers that these bodies are a hitherto unknown form of blood parasite, resembling those described by Edelmann. The only differences between Schur's and Edelmann's cases were the degree of leucocytosis and the size of the enlarged spleen. Antiparasitic treatment with quinine and stovarsol was employed, the temperature fell and the systolic bruits and splenic enlargement disappeared. The patient gained weight, and the blood count became normal, except that a moderate eosinophilia (6 per cent) persisted.

328 Vincent's Infection of the Nose.

H I SHULMAN (*Amer Journ Dis Child*, August, 1928, p 35) who records an illustrative case of Vincent's infection of the nose in a boy aged 3 remarks that nasal discharge mixed with blood particularly when it has been persistent, is so often associated with diphtheria and a foreign body that little attention is usually paid to other conditions. The symptoms of Vincent's infection of the nose are a persistent mucopurulent discharge and a greenish membranous slough. The discharge has a foetid odour and tends to excoriate the skin. The nose is tender to touch, and this renders examination difficult. The condition may be associated with Vincent's infection of the gums, as in Shulman's case, it is accompanied by cervical adenitis, slight rise of temperature, rapid pulse, irritability, and restlessness. Treatment consists in swabbing the nose with half strength hydrogen peroxide, followed by 5 per cent chromic acid, which is kept in the nostril for a minute. Only one previous example of Vincent's infection of the nose, reported by Place in 1911, is on record.

329 Polycythaemia Vera.

AFTER discussing the various forms of polycythaemia, such as those due to high altitudes, chemical agents, and congenital heart disease, G A HARROP, jun (*Medicine*, August, 1928, p 291), deals fully with polycythaemia vera. This disease, which seemingly is a constitutional or familial malady, affects both sexes equally, and is more common than hæmophilia, as is the case in pernicious anaemia, and its onset is usually in middle or late middle life. The patients present a rather characteristic body build, being usually spare with thin and often narrow faces. The disease is marked by a clinical syndrome of chronic cyanosis of a peculiar and striking hue, epistaxis, and polycythaemia. The cyanosis occurs especially on the exposed surfaces—namely, the face, particularly the cheeks, the tip of the nose, and the ears, the trunk usually being unaffected. Paraesthesias, typical of the disease, may be due to the plethora and stasis of the blood in the peripheral vessels. The superficial appearance of the eyeballs is often striking and the retinal picture is well known. Enlargement of the spleen is by no means constant, and the polycythaemia is usually supposed to antedate the epistaxis. Gastro-intestinal symptoms are very prominent, the most serious being hæmorrhages, severe bleeding is one of the principal causes of death. Associated with the portal thrombosis are other liver disorders, including enlargement and cirrhosis, a rather common terminal event. Nervous

and p. yohio disturbances are often the first and most striking manifestations of the disease, the chief being lassitude, headache, vertigo and giddiness, transient syncope, insomnia, weakness, a sensation of fullness in the head, numbness and tingling in the fingers, but less often in the feet, burning sensations, and extreme sensitiveness to cold. Of the pathological changes, extensive hyperplasia and proliferation of the red bone marrow is of primary otological importance. The blood shows the following changes: very great concentration of erythrocytes per unit of volume, with a most marked increase in the total blood volume, much intensified viscosity, normal or somewhat delayed clotting time, and unaltered haemoglobin. Anisocytosis, microcytosis, polychromasia, normoblastosis, and less frequently megaloblastosis, are often found. Many therapeutic measures, such as oxygen therapy, venosuction, and bouzou, have been found to be useless. Phenyl hydrazine, given over a period of several days, has proved of benefit in some cases. Good results have followed radiation (both x-ray and radium), but this apparently should be applied over the long bones only and not be directed to the spleen. Splenectomy is absolutely contraindicated. Two hypotheses are advanced to explain the bone marrow changes. The first regards polycythaemia vera as primarily a disease of the red marrow, strictly analogous to leukaemia—that is, it is a type of malignant tumour, the second considers the bone marrow changes as secondary to one or several different factors causing over stimulation.

330 Recurrence of Herpes Zoster

ACCORDING TO J. VERGELY (*Journ de Méd de Bordeaux*, August 25th, 1928, p. 632) it is generally held that herpes zoster is a disease which does not recur, one attack conferring immunity for the rest of life. O. W. Allen, however, in 1898 reported a case of a girl, aged 13, who developed lumbo-abdominal zoster in 1898 and thoraco-brachial zoster on the same side the following year. Vergely now records the case of a previously healthy woman, aged 30, who developed typical right dorso-brachial zoster in July, 1923. In November, 1927, while still in good health apart from overwork after being in contact with two children suffering from varicella, she had a typical attack of herpes zoster in the corresponding region of the opposite side. Vergely does not discuss the question as to whether the first attack was essential zoster and the second the result of infection by varicella, but expresses the opinion that zoster—like other diseases, such as measles and small pox, which usually confer immunity—is occasionally liable to recurrence. In such cases the disease, either from insufficient virulence or lack of reaction on the part of the individual, fails to provoke a sufficient quantity of antitoxin to allow the patient to escape a second infection.

331 Immunization against Diphtheria.

J. A. MUÑOYERRO (*Arch. d-med. cir. y esp.*, September 22nd, 1928, p. 334) states that immunization against diphtheria with anatoxin is absolutely harmless, no fatal case having yet been recorded among the many thousands which have been inoculated with it in Europe. Among 1,500 personal cases he has not met with a single instance of a violent reaction or disagreeable sequelae. He urges that immunization with anatoxin should be made compulsory like vaccination against small pox, so as to prevent the annual death toll of more than 4,000 children in Spain due to diphtheria. The most suitable age is 1 to 2 years, but up to the age of 5 years immunization should be performed without a preliminary Schick test. After that age only those found to be susceptible by the Schick test need be inoculated. During epidemics of diphtheria those who have not been immunized should be injected with serum, and three weeks later should be given three doses of anatoxin, with an interval of three weeks between each dose. Those who have been already inoculated should be given another injection of anatoxin if it is not desirable to perform a Schick test. Almost every child who has been given three doses of anatoxin may be regarded as immune to diphtheria. Muñoyerro found only 2 per cent who were refractory after three doses, and these became immune after the fourth dose.

332 Gallop Rhythm in Hypertension.

A. DUMAS (*Journ de Méd de Lyon*, September, 1928, p. 543), discussing the origin and significance of gallop rhythm, emphasizes the fact that in all cases it represents abrupt reduction of the arterial blood pressure, irrespective of the original tension. Thus it may occur simultaneously with sudden weakening of the myocardium, or alterations in the peripheral circulation. Both the gallop rhythm supervening in hypotensive states and that accompanying hypotension depend for their production upon increased diastolic relaxation of the ventricular wall, which oscillates with the impact

of blood forced into the ventricle during auricular systole. This explanation holds good whether the gallop is presystolic or diastolic, the different time relations of the added sound and the first heart sound in the latter case depending upon prolongation of the PR interval and defects of myocardial contraction, these factors most clearly operate in the diastolic gallop so frequently observed in myocardial infarction. Etiologically, gallop rhythm in hypotension may be classified as occurring as three types: the first consists of those cases in which gallop is of cardiac origin, such as primary cardiac enlargement unrelated to arterial hypertension and myocardial infarction, the second group depends upon peripheral or vascular causes, such as haemorrhage, vaso-dilatation attending shock, and hypotensive states—for example, those related to endocrine disturbances, the last group is seen typically in typhoid fever and other infectious diseases. Ordinarily in these diseases no gallop is present, its appearance, therefore, is frequently of grave import as indicating myocardial insufficiency or the onset of circulatory failure.

Surgery.

333 Teratomatous Cysts of the Spinal Cord

L. S. KUBIE and J. F. FULTON (*Surg., Gynecol. and Obstet.*, September, 1928, p. 297) report a clinical and pathological study of two cases of teratomatous cyst of the spinal cord containing mucus and ciliated cells. One, a boy aged 2, was brought with a history of always having dragged the right foot, with later irritability and a "tender" abdomen. Repeated lumbar punctures between the tenth and eleventh dorsal vertebrae gave vent to thick "egg white" fluid filled with ciliated cells. At the operation a flattened cyst was found extending on the dorso-lateral surface from the tenth dorsal to the fourth lumbar vertebra, it proved to be a simple teratoma lined with ciliated columnar epithelium. Complete recovery followed its removal. The other patient was an unmarried woman, aged 27, who, since the age of 2, had had five attacks of left hemiplegia with pain in the left cervical region and Brown Séquard dissociation of sensation in trunk and extremities. The last attack produced an almost complete quadriplegia with an upper level of sensory disturbance at the fourth cervical vertebra, the respiration was gasping, laboured, and entirely diaphragmatic. At the operation a cyst filled with mucus and ciliated cells was removed, it was attached to the left side of the cord at the junction of the third and fourth cervical vertebrae. This proved to be a more complex teratoma than that of the other case reported, with changes compatible with its greater duration. Immediate recovery of power resulted after its removal, with marked, though less complete, return of sensation. In both cases the cysts were congenital, and probably represented ependymal diverticula of the central canal of the cord. Some instances from the literature presenting analogous features are reported, though a careful search gives no record of cases exactly comparable.

Cleft Palate.

W. E. M. WARDILL (*Brit. Journ. Surg.*, July, 1928, p. 127) describes a new operative procedure for cleft palate. The operation is divided into two stages, the object of the first being to narrow the nasopharynx laterally and to produce a union of tissue on the posterior pharyngeal wall, imitating but exaggerating that which is formed by the superior constrictor muscle, in order to form a seating for the upper surface of the repaired soft palate. The mucous membrane is incised transversely at the level of the ridge of Passavant, and is held open with fine sharp hooks. The bucco-pharyngeal fascia being relatively tough, the superior constrictor muscle and covering mucosa can be peeled from it. The dissection is carried on in this layer upwards almost to the base of the skull, downwards for a similar distance, and laterally a little beyond the ridge of the salpingo-pharyngeus muscle. The incision is enlarged laterally up to the salpingo-pharyngeus, and is sewn up in a vertical direction. The second stage is the repair of the palate, and this part of the operation is usually performed after an interval of three to four weeks. The Langenbeck-Ferguson method is the one used most effectively, with the modification of the division of the hamular processes or of the tendons of the tensors of the palate, thereby setting free the palatal aponeurosis and so destroying the greatest bar to backward displacement of the palate. The author adds that care must be taken until recovery from the anaesthetic is complete, since repair of the palate blocks the nasopharynx until the sutures loosen. In six cases out of eight a functional pharyngeal valve was formed, and evidence showed that speech was improved. The operations were, however, of too recent a date for it to be certain that the

oushion formed on the pharyngeal wall would persist. It is thought that the method of operation may be applicable to infants, though the youngest patient (aged 4) died after the operation from acetonaemia.

335 Metacarpal Fractures.

D DAMI (*Rev Méd de la Suisse Romande*, September 25th, 1928, p 794) asserts that in certain cases of fracture of the metacarpal bones reliance on radiography may lead to diagnostic errors. The true condition can be ascertained solely by clinical examination, and three cases are reported illustrating this contention. At the first these fractures are characterized by simple contusion, with partial loss of power in one or more fingers, and diffuse pain. When the swelling has diminished pathognomonic signs appear, those being intense pain at the site of the fracture, crepitation, which, however, is inconstant, more rarely, abnormal mobility due to displacement of the fragments, and, especially in fractures of the second and fifth metacarpals, which have lost lateral support, lateral displacement which causes an apparent deformity of the segment of the hand involved. The seat of election of these fractures is the diaphysis, direct fractures are usually transverse, and indirect ones commonly oblique, running from below forwards. The latter, the most frequent, may present either a straightening (rarely) or an exaggeration of the normal curvature of the bone. The metacarpal osteomyelitis, especially the first, may also be fractured. There are three types of these: the fracture of Lenoir (boxer's fracture), in which the head of the first metacarpal is fractured, that of Bonnot, at the base of the first metacarpal and involving the trapezometacarpal articulation, and that of Rolando, in which the base of the first metacarpal is broken into three fragments, separated by a Y shaped line of cleavage. Dami comments on the difficulty of obtaining exact radiographs of these forms of injury.

336. Pseudomyxoma Peritonei

J NAESLUND (*Uppsala Läkartidskrift*, Förhand, June 16th, 1928, p 1) states that this condition is relatively uncommon, as barely one hundred cases have been recorded, though it is not so rare as some authors maintain. A close study of the literature shows that it is by no means predominant in men and exceptional in women, but that both sexes are almost equally affected. Naeslund, by removing the appendix from the rest of the alimentary canal in newborn rabbits, succeeded in producing experimentally large tumours, occasionally provided with diverticula, some of which burst and discharged their contents into the abdominal cavity. Subsequent examination showed the presence of cysts filled with mucus, either free in the abdominal cavity or attached to the omentum or coils of the small intestine. These experimental changes correspond to what is known of the pathology of mucocoele, appendix and pseudomyxoma peritonei or processus vermiformis in man.

337 Pancreatic Calculus.

A W MEYER (*Zentralbl. Chir*, September 29th, 1928, p 2440), who records an illustrative case, remarks that pancreatic calculi are rare. N Guleke has collected 50 cases from the literature and v. Schuleden has reported 20 operations, of which 11 were successful, for the removal of calculi in the pancreas. Meyer's patient, whose age and sex are not stated, in addition to a feeling of compression in the epigastrium, showed disturbance of internal secretion in the form of fatty stools. On x-ray examination a calculus was seen in the pancreas. Laparotomy was performed and the calculus was removed through an incision in the pancreas about 3 to 4 cm long. Complete recovery followed.

338. Vertebral Trauma followed by a Polymyelitic Syndrome.

R LOMBARDO (*Studium*, September 20th, 1928, p 411) discusses the similarity which may exist between certain traumata of the vertebral column and the syndrome of anterior polymyelitis, and reports an illustrative case. A boy, aged 14, was struck violently on the back and fainted. There was a contusion with excoriation from the thorax to the occiput, and a deep wound in the region of the right carotid. For some days the boy remained unconscious and collapsed, with general muscular relaxation. Later, complete paralysis of the right upper limb and limitation of neck movements were observed. There was incomplete paralysis of the right lower limb. The patient remained in hospital in a debilitated condition for some time. Eight months afterwards there was paralysis, with wasting of the muscles of the shoulder girdle and of the right arm. The right leg was not obviously affected, though there was a slight impediment in walking. All the measurements of the arm showed a considerable degree of wasting, as did the small muscles of the hand. There was a diminution in the reaction to faradic and galvanic stimulation. The deep reflexes were increased and the Babinski sign was present on the side of the paralysis.

There was no disturbance of the sensory organs, and the psychical functions were normal. So far the clinical picture might have been that of a localized affection of the anterior horns. In the right carotid region there was an irregular scar, adherent to underlying tissues and having a fistula from which escaped a sero-purulent discharge. A radiogram showed a foreign body lodged at the level of the transverse processes of the sixth and seventh vertebrae. At an operation two metallic plates of the size of a halfpenny were removed. The post-operative course was normal and the wound healed in fifteen days. On examining the patient three months later it was found that the nervous syndrome had not been modified, except that there was rather freer movement of the head.

339 Post-operative Jejunal Ulcer

N M ALLEN (*Amer Journ Surg*, August, 1928, p 128) reports cases of jejunal ulcers occurring after gastro-enterostomy. He finds that post-operative marginal or jejunal ulcers appear most frequently near the suture line, the symptoms being emaciation and a secondary anaemia, the duration of relief after ingestion is shorter than when a duodenal or gastric ulcer is present, there is pain in the region of the mid portion of the transverse colon, and the disease is more incapacitating than in the case of a primary ulcer. Sometimes the marginal ulcer occurs as soon as seven months after gastro-enterostomy, but cases have been reported in which it developed fourteen years after the operation. The cause may be any of the following: the use of clamps during the original operation, the use of non-absorbable suture material, faulty placing of the anastomosis, haematoma becoming infected and causing inflammation, infiltration, and possible ulceration, focal infection, and operation on mistaken diagnosis. When the primary operation was gastro-enterostomy treatment involves the disconnection of this, the resection of the ulcer, and repair of the jejunum and stomach if there is no stenosis in the pylorus. Marginal or jejunal ulcers occur as frequently after partial gastrectomy as after gastro-enterostomy, and present a more formidable surgical procedure than when a simple gastro-enterostomy has been performed. Out of eleven cases of marginal ulcer, one patient had six operations, two had four, and one had two. The conclusion is drawn that the type of operation and surgical procedure had nothing to do with the recurrence of the ulcer.

340 Primary Adeno carcinoma of the Epididymis

A J SCHOLL (*Journ Amer Med Assoc*, August 25th, 1928, p 380), who reports an illustrative case, states that tumours of the epididymis were classified by Hinman and Gibson in 1924 into benign tumours consisting of the three groups: epithelial, (2) mesoblastic (lipoma, fibroma, myxoma, and (3) leiomyoma), and (3) heterologous (cystodermoids), and malignant tumours—epithelial (carcinoma), mesoblastic (sarcoma), and heterologous. Only twelve cases of benign tumour of the epididymis are on record, the varieties being leiomyoma, which is the most frequent, while there are isolated examples of lipoma, fibroma, adenoma, and fibromyoma. Hinman and Gibson found only three cases of carcinoma and ten of sarcoma in the literature. Tumours of the epididymis are more frequent on the left side and the site is usually the tail or the corpus, a tumour has never been found in the head of the organ. Scholl's patient was a man, aged 22, who developed pain of the right testis, which set in three months after an injury, and was followed by swelling of the organ five months later. The scrotal contents were very sensitive and constantly painful. A diagnosis of epididymitis was made. An operation was performed under local anaesthesia, when the epididymis presented the nodular and reddened appearance of tuberculous infection. Microscopical examination, however, showed the presence of malignant disease of the nature of adeno-carcinoma. The epididymis, testis, surrounding coverings, and cord, up to the external inguinal ring, were removed. Three months later there was recurrence at the site of the wound, and a further operation was performed. Four months afterwards the patient developed signs of pleural effusion in which numerous apparently malignant cells were found. The issue of the case is not recorded.

341 Injection Treatment of Varicose Veins

R MENA (*Arch de méd. cir y esp*, September 29th, 1928, p 349) reviews the literature, and records fifteen cases of varicose veins treated by injection of 3 cm of sodium salicylate in a 20 to 40 per cent solution. No symptoms of shock were produced, and only one patient complained of feeling faint at the time of the first injection. Relief was experienced after five or six injections, and eight or nine were generally sufficient to produce sclerosis of all the varicose veins. The treatment is said to be undesirable in patients in whom varicose veins indicate a collateral circulation, as in abdominal tumours, ascites, and old deeply seated phlebitis.

Therapeutics.

342. Tryparsamide in General Paralysis

R C JARNIKE and G W FORMAN (*Journ Nerv and Ment Dis*, September, 1923, p 261) report the treatment with tryparsamide of 100 patients suffering from paralysis who were in poor physical health and presented marked mental deterioration. Each received an average of 34.6 injections of tryparsamide of 3 grains each. The best results were obtained in twenty-six cases where the condition had lasted less than three months. Improvement in most cases was noticed after the first six weeks to two months of treatment, and nearly always began with a gain in weight, mental improvement following later. By a long continued administration of tryparsamide clinical and serological cures were produced in five cases, and clinical and mental improvement in thirty-eight. No complications occurred in a few and headache was occasionally noticed, but was not severe or of long standing. The authors remark that in spite of the fact that the spirochaetal action of this drug is comparatively low, its marked impermeability and its power of reinforcing the natural processes of resistance bring about an obvious clinical improvement which entitles the drug to a prominent place in the treatment of this resistant disease, although complete cure is relatively rare. The patients presenting manic symptoms at the time of admission showed the most rapid and complete return to the normal.

343. The Manganese Treatment of Pneumonia.

F S COOMBS (*Med Journ of Australia*, August 11th, 1928, p 175), from a personal experience of nineteen cases advocates the treatment of pneumonia by rectal injections of potassium permanganate. From 3 to 10 oz., according to age, of a solution prepared by dissolving 2 grains of chemically pure potassium permanganate in a pint of water are injected slowly through a funnel and tube of small bore at a temperature of 105° F., the patient's buttocks being raised on a pillow. These injections are repeated every two and a half to four hours for the first twenty-four to thirty-six hours, the intervals between the injections depending on the day of the disease on which treatment is commenced. The earlier the patient is seen the longer the interval, the less the injections are retained the more frequently must they be given. Once the temperature becomes normal the injections should be given twice a day for three days and then once a day for three days. It is claimed that within a few hours after the first injection the breathing becomes easier, deeper, and slower, and the cough freer, with less tenacious sputum, the rusty appearance of which gives place to a white frothy expectoration which may be ushered in by a small haemoptysis. The temperature drops to normal or to a lower level soon after the first or second injection, and the appetite returns even earlier. Coombs contends that this treatment provides an excellent chance of aborting the attack, especially in children, if commenced quite early.

344. Intravenous Use of Digitalis Preparations

H E B PARDEE (*Journ Amer Med Assoc*, July 21st, 1928, p 147) has made a clinical investigation of the therapeutic action of intravenous injections of digalen, digitan, and digitfolin. Each of these substances was administered in doses of 1 minim per lb of body weight. Three groups of patients were thus treated, the retardation of the heart rate being taken as the index of digitalis action. In the group treated with digalen a marked slowing was noted fifteen minutes after the injection, the pulse rate continuing to fall for another two hours. The group of patients treated with digitan and digitfolin showed similar but slightly less rapid effects. Other observers have investigated the action of intravenous strophanthin in a similar manner and found that the maximum effect was produced earlier, though the initial effects did not appear so quickly. With regard to oral and rectal administration of the digitalis preparations, doses equal to or larger than those given intravenously failed to produce the same effect. The author considers intravenous digitalis therapy to be indicated only when the patient is so ill that prompt results are necessary, or when the patient cannot retain digitalis by mouth or rectum. For a patient who has had no digitalis for two weeks the dose of those preparations should be 1 minim per lb of body weight. If there is no improvement in two hours a further dose equal to one fourth of the original should be injected. As many as four such additional doses may be given in the absence of clinical improvement or toxic effects. The latter include, besides slowing, acceleration and irregularity of the heart occasionally. A patient who has recently had digitalis must be

treated cautiously and given doses of $\frac{1}{2}$ mg per lb of body weight every thirty or forty minutes until a result is shown. Not more than four such doses may be given. As compared with strophanthin, the intravenous use of digitalis preparations is preferable because of the wider margin between the slight and marked toxic doses. Comparing the effects of intravenous, intramuscular, and hypodermic injections, the author considers that delay in absorption may occur in the last two methods owing to feebleness of the circulation in cardiovascular diseases.

345. Treatment of Endocrine Disorders in Infancy and Childhood

L F BARKER (*Amer Journ Dis Child*, May, 1928, p 872) remarks that true ophthalmic goitre has occurred as early as the third year of life, and many cases have been reported between the ages of 3 and 10. Besides the classical symptoms, emaciation, sweating, diarrhoea, mental and physical restlessness, with an accelerated basal metabolic rate, should be kept in mind. Treatment includes the correction of faulty hygiene, the temporary exhibition of bromides or phenobarbital, and thyroidectomy. Childhood myxoedema is much more common. In severe cases the transposition of a piece of ophthalmic thyroid is suggested. The treatment of colloid goitre, in regions where it is endemic, with minimal doses of iodine, is commended. In tetany resulting from a deficiency of parathyroid function there is an associated diminution of the calcium content of the blood. A potent parathyroid extract, which will raise the level of the blood calcium rapidly, is indicated. It is not yet established, however, that all tetany is of hypoparathyroid origin, moreover, cases of marked hypocalcaemia occur without tetany. Hypoparathyroidism has been experimentally produced in dogs, with consequent hypocalcaemia, vomiting, drowsiness, pallor, atony, and circulatory failure. A 25 per cent solution of dextrose is suggested as an antidote. Gigantism and acromegaly, dwarfism and dystrophia adiposogenitalis, and diabetes insipidus are associated with dysfunction of the pituitary gland. Treatment by surgical measures, substitution therapy, and radiation is far from satisfactory. With marked thymus enlargement asphyxiation seizures are observed, there may be simple syncopeal attacks, persistent cyanosis, or asthmatic attacks. These have been variously ascribed to pressure and to thymic intoxication. X-rays serve both for diagnosis and for therapy. In the status thymico-lymphaticus a large thymus, marked lymphocytosis in the blood, and very large medial and very small lateral incisor teeth in the upper jaw are described. The importance of the thymic function in the development of the genitals is suggested. Hyperplasias or neoplasms of the suprarenal cortex are held to account for pseudohermaphroditism and premature puberty. The enchondroid phenomenon so often seen in boys with undescended testicles almost certainly depend on a deficiency of the internal secretion of the sex glands. An accidentally induced hypoglycaemic shock syndrome, characterized by convulsive seizures or by transient loss of consciousness, may easily develop in the treatment of diabetic cases with insulin. Cases of spontaneous hyperinsulinism and hypoglycaemia have been recorded. One group of hyperglycaemic cases is refractory to insulin, the cause is not always apparent.

346. Bismuth Arsphenamine Sulphonate in Syphilis

P A O'LEARY (*Arch Derm and Syph*, September, 1928, p 372) records his experience during the last eighteen months with bismuth arsphenamine sulphonate administered intramuscularly into the buttocks in the treatment of syphilis, he uses 0.2 gram doses dissolved in 1.0 c.c. of sterile water with 2 minims (0.1 c.c.) of a 2 per cent solution of bityn for its local anaesthetic effect. In acute syphilis four courses, each consisting of eight injections, were given, the injections being made on every fourth day with a rest period of four weeks between each course. Local reactions are said to be practically negligible, and the addition of bityn removes any complaint of discomfort. Constitutional reactions were mild, and only one instance of exfoliative dermatitis occurred in eighty-four cases, there were no such complications as jaundice, hepatitis, encephalitis, kidney infection, neuritis, syphilitic neurorecurrences or blood dyscrasias. The drug has apparently a slower therapeutic and spirochaetocidal effect than is the case with other preparations of arsphenamine. While the serological studies of the blood in cases of acute syphilis are gratifying further research is necessary before their value in early neurosyphilis can be determined, the question whether mercury should begin simultaneously is still undecided. O'Leary found that six of his cases in which mercury injections were not so given progressed as well, both clinically and serologically, as those in which they were given.

347 Vaccine Treatment of Cerebro spinal Meningitis

L M M E MORFET (*Thèse de Paris*, 1928, No 299) remarks that the increasing number of failures of antimeningococcal serum in the treatment of epidemic cerebro spinal meningitis has led to the trial of other measures, especially vaccine therapy. Intramuscular or intraspinal injections of meningococcal endoprotein, of which a description was recently given by Luton, have yielded fairly satisfactory results, except in infants, and, in spite of the violent reaction which they provoke, appear to be free from any danger. The injections of endoprotein may be given in association with serum treatment or alone, the latter method seems to be the best. Previous intrathecal injections of serum, however, are a contraindication to the use of endoproteins. Intramuscular injections of endoprotein are an effective means of controlling the symptoms of meningococcal infection, especially the pseudo malarial fever. Intrathecal or intramuscular injections of endoprotein only appear to be effective when they produce a fairly intense reaction. This reaction does not appear to be specific, but rather of the nature of protein shock. The author reports the histories in eight cases of cerebro-spinal fever in patients aged from 6 months to adult life, who were treated by intramuscular or intrathecal injections of meningococcal endoprotein with or without antimeningococcal serum. Four recovered and four died, the ages of the fatal cases ranged from 6 months to 3 years, while those who recovered were aged 13 and 14 or were adults.

Radiology.

348. Uncertainty of Cholecystography

W W BOARDMAN (*Amer Journ Med Sci*, September, 1928, p 383) warns against diagnosing a pathological condition of the gall bladder on the unsupported evidence of the tetradiodophosphthalcin test. He points out that for successful visualization of the gall bladder there must be sufficient concentration of the dye in the blood stream, a liver capable of excreting it, patent common and cystic ducts, a gall bladder capable of receiving, concentrating, and discharging the dye, and a properly functioning sphincter mechanism at the lower end of the common duct. Disturbance in any one of these factors results in a partial or complete failure of gall bladder visualization, yet several of them are entirely independent of the anatomical condition of this organ, and may vary from day to day, thus giving contradictory results if the test is repeated. Radiographical findings should be interpreted in terms of the functional activity of the biliary system, rather than in terms of the pathology of the gall bladder. He adds that, though radiological examination of this kind is of the greatest aid in the study of the functional activity of the biliary tract, careful correlation of the results with the other clinical findings is absolutely essential to proper diagnosis and treatment.

349 WITH a view to improving cholecystography as a diagnostic procedure W H STEWART and H E IBELICK (*Radiology*, October, 1928, p 271) plead for standardization at technique in the oral method so that a 12 or 16-hour film may be universally understood. They recommend the administration of a mild cathartic the night before the preliminary examination, which should be made in the afternoon before any of the dye has been given, the patient's activity during the subsequent examination need not be curtailed, since it does not affect the results. A pure and fresh preparation must be used, and at the time of the preliminary examination the 3.5 grams of tetradiodophosphthalcin contained in one sealed coloured glass ampoule are transferred into eight plain gelatin capsules. These, together with four 10 grain capsules of sodium bicarbonate, are given to the patient, who is instructed to eat, at 6 p.m., a meal consisting of soup, creamed chicken or soft boiled eggs, vegetables, bread and butter, and a glass of milk, and at 9.30 p.m. to swallow two of the tetradiodophosphthalcin capsules and one of the sodium bicarbonate capsules with half a glass of water every quarter of an hour until all have been taken. He is instructed to report himself at 9.30 the following morning, without having had any food, and the 12-hour examination is made, and, still starving, the 16-hour examination follows at 1.30 p.m., after which a lunch consisting of two soft-boiled eggs, two pieces of well buttered toast, and a cup of tea is taken, to be succeeded an hour later by the 18-hour examination. After an evening meal the patient reports the next morning at 9.30 for the final 36-hour examination following which a barium meal examination is made of the stomach, duodenum, and hepatic flexure for evidence of adhesions or associated lesions. At the preliminary examination calcified calculi may be detected, and any doubtful shadows can be checked later by the gall bladder shadow

after the dye. The fatty meal the night before the 12-hour examination ensures the gall bladder being as empty of bile as possible when the dye is given, so that as the gall bladder fills during the night its greatest concentration may be present at the 16-hour examination. The lunch an hour before the 18-hour examination tests the emptying power, and at the 36-hour examination the shadow should have completely disappeared. Any variation from such a normal cycle of filling, concentrating, and emptying should arouse suspicions at there being some impairment of functional efficiency with a pathological lesion.

350 Radium Treatment of Rectal Cancer

G E BINKLEY (*Radiology*, June, 1928, p 457) classifies patients with rectal carcinoma as favourable or unfavourable, according to the general condition of the patient, the site of the growth, radio-sensitivity and degree of malignancy of the tumour, and extension of involvement by the tumour cells. He advocates radium as the principal factor in treatment for practically all cases. The most efficient method of radiating rectal cancer is by careful and uniform implantation of gold emanation seeds into the tumour mass. Although less efficacious than emanation seeds, external radiation is the first step in treatment, it is applicable to all cases and determines the tumour radio-sensitivity. The erythema dose is given at a distance of 10 to 15 cm from the skin through several portals of entry. Binkley submits the results in 103 patients admitted to hospital from July, 1925, to July, 1927—23 favourable and 77 unfavourable. Of the former group 18 are free from recognizable rectal cancer. In the latter group, of 20 patients who received extensive palliative treatment 18 are still alive and 17 were greatly benefited. Of 34 found suitable for mild palliation only, 30 were benefited, and 13 of these have survived.

Obstetrics and Gynaecology.

351 Complications of Myoma.

HEIMANN (*Zentralbl f Gynäk*, August 4th, 1928, p 1996) records two cases of myoma with complications. A woman, aged 30, was treated by excision of the hymen and vaginal dilatation for dyspareunia shortly after marriage. Eight weeks later the uterus was found to be hard and enlarged to the size of the fist. Amenorrhoea for six weeks was reported, accordingly the patient was treated expectantly for three weeks, when the soft pregnant uterus was found to be distinguishable from the hard myoma. Delivery occurred spontaneously at term, but manual removal of the placenta was necessary four hours later for post-partum haemorrhage. The placenta was very firmly attached to the anterior wall in the neighbourhood of the myoma, this growth, which was as large as a fist, was spontaneously expelled on the sixteenth day of a pyrexial puerperium. At a later date all morbid signs and symptoms had disappeared. The second patient was a single woman, aged 39, one of whose breasts had been amputated for sarcoma eleven years previously. She complained of excessive bleeding, and was found to have an enlarged myomatous uterus, caretting showed hyperplastic endometrium without suspicion of malignancy. After eight months of regular two-day menstruation at four to six day intervals a thin blood stained discharge was noted, and the uterus was found to have undergone considerable enlargement in the zone of the previously noted myoma. Sarcomatous degeneration of the myoma was suspected and total extirpation was performed. The uterus was found, however, to contain a large carcinoma of the body, which must have developed in eight months.

352. Haemorrhagic Metropathy of the Menopause

E TARAMELLI (*Ann di Ostet e Ginecol*, May 31st, 1928, p 539) believes that "metropathia haemorrhagica" of the menopause should be considered as a definite clinical entity on account of its mode of onset the age of the patient, its clinical course, and the haematological, gynaecological, and anatomical pathological findings. Taramelli considers this condition to be a general disturbance of the neuro-endocrine system, of menopausal or pre-menopausal origin, which produces local modifications in the walls and vessels of the uterus, thus leading to metrorrhagia. He claims that radium therapy is the method of choice and that the brilliant results already obtained guarantee a permanent cure. The effects of the intrauterine application of radium should, he thinks, be referred mainly to direct influence on the uterine wall and its vessels, and in a minor degree to a less direct effect upon the ovary and on the general endocrine equilibrium, as well as to modification of the blood plasma, which becomes endowed with new stimulating powers. As the result of the application

of radium the blood pressure is modified so as to approach the normal, being diminished if too high and increased if too low. The coagulation time of the blood is also changed in the same manner. Radio activity augments the number of erythrocytes and leucocytes, and the renal functions are also modified. After the intratracheal application of radium there are habitually lacking symptoms attributable to the sudden cessation of ovarian functions concomitant with the resulting amenorrhoea.

353. Tumours of the Great Omentum in Women

E. M. FUSS (*Centralbl. f. Gynäk.*, July 14th, 1928, p. 1782) refers to the importance of distinguishing tumours of the great omentum from other abdominal conditions. Indications of involvement of the omentum are the detection by palpation of a tumour mass not in the abdominal wall but under it, and yet appearing to be near to the examining fingers, definitely separated from the pelvic organs, and having no demonstrable connexion with the stomach, kidney, gall bladder, or bowel. The diagnosis is strengthened if the tumour is unusually freely movable, and especially if dullness or tympanicity of an underlying organ can be detected through the tumour. Confirmatory evidence is afforded by any history of a previous laparotomy for an inflammatory condition or hernia, especially where omentum had been resected. Fuss thinks that omental tumours are commoner than is usually supposed. They may be inflammatory, non-inflammatory, benign, or malignant. The omentum is involved in all inflammatory processes, and may be the seat of inflammatory and hyperplastic tumours long after recovery from the primary illness or operation. Fuss recommends that conservative treatment should be tried first, if after one to one and a half months the tumour persists an operation should be undertaken, particularly since it is impossible to eliminate malignant disease from the diagnosis by external examination. Operation is necessary where the tumour is causing ileus or torsion, or is due to actinomycosis, all non-inflammatory tumours require operation. Haemorrhagic ascites is said to be an almost certain sign of malignancy. The author adds that an operation for a malignant growth should be thorough, even to removal of the whole omentum, for, in spite of the risk of metastasis and recurrence, good results have been reported in some very advanced cases.

354. Diagnosis of Foetal Age from Ossification Centres.

V. CATHALA and Mlle J. BARDY (*Bull. Soc. d'Obstet. et de Gynéc. de Paris*, July, 1928, p. 601) point out that the data found in textbooks of obstetrics or forensic medicine, according to which the age of the foetus may be inferred from the presence or absence of ossification centres in certain bony epiphyses, are reliable for a majority of cases only, the foetal age and the ossification phenomena have been correlated from two variable and unreliable factors—namely the physical characters of the infant and the menstrual history of the mother. The authors have made x-ray examinations of the femoral and tibial epiphyses at the knee joint in thirteen pairs of newborn univitellic twins, and in ten cases have found distinct differences in the ossification, one or both centres being less well developed or absent in the infant having the lesser body weight. In one instance the age of one twin, as calculated from the ossification phenomena, was seven months gestation, that of the other eight and a half to nine months gestation. It is concluded that in forensic medicine epiphyseal ossification affords no certain index of foetal age, and the absence of Bédard's point in a newborn child weighing less than 2½ kilograms does not indicate prematurity. These observations show also that differences of ossification in bivitellic twins afford no evidence of superfoetation.

Pathology.

355. The Relation between Glycaemia and Temperature.

WHILE it is generally admitted that glycaemia is related to the thermo-regulating mechanism of the body, A. DE CARVALHO (*C. R. Soc. de Biologie*, September 18th, 1928, p. 935) states that this subject has not been sufficiently studied, and records the results of a series of his own experiments. Those were performed on non-diabetic subjects after a fourteen hours' fast to whom various antipyretics were administered. Before administration the temperature and blood sugar were ascertained. After it, the temperature was noted every five minutes, and, when the effect of the drug was at its highest, one or more samples of blood were taken for the estimation of the sugar by Hagedorn's method. The antipyretics employed were antipyrin, pyramidon, quinine,

and oryogouline. As a result of 59 such determinations, de Carvalho concludes that hyperglycaemia does not occur during the course of fever, and that there is no relation between the oscillations of temperature and those of glycaemia.

356. Lymphatic Reaction following Varicella.

A. VAN WESTRIJENEN (*Nederl. Tijdschr. v. Geneesk.*, August 18th, 1928, p. 4015) states that recently considerable attention has been paid to the occurrence of a lymphatic reaction following infections, especially tonsillitis, and the difficulty in distinguishing it from lymphatic leukaemia. He records a case of a girl, aged 6, who a fortnight after an attack of chicken pox showed a leucocyte count of 22,000, of which 80 per cent. were lymphocytes. The spleen and liver were enlarged and the temperature was raised sometimes as high as 102.2°. Five days later the leucocytes fell to 6,800 of which 85 per cent. were lymphocytes. The lymphatic glands were not affected and the red corpuscles showed nothing abnormal. In the course of the next few months the number of leucocytes ranged between 6,000 and 7,000, and the lymphocytes gradually fell to 52 per cent. Another striking change was the occurrence of eosinophilia, which lasted for seven months and rose as high as 13 per cent. An uncomplicated attack of scarlet fever which occurred about six months after the onset of chicken pox was followed by disappearance of the eosinophilia and a fall in the lymphocytes to 46 per cent.

357. Natural Immunity to Diphtheria.

G. RAMON, O. NOUREDDINE, and B. ERBER (*C. R. Soc. de Biologie*, July 27th, 1928, p. 562) point out that the guinea pig and the pigeon are highly susceptible to diphtheria toxin, whereas the rat is resistant. A dose of 1/1000 c.c. of toxin suffices to kill a guinea pig weighing 250 grams, and a dose of 1/500 c.c. of a pigeon of the same weight, but to kill a rat about 0.75 to 1.0 c.c. is required. Moreover, in the guinea pig a dose of 1/5000 c.c. injected subcutaneously produces oedema and necrosis, and a dose of even 1/100,000 c.c. intradermally a definite skin reaction, but in the rat a dose of 0.25 c.c. injected subcutaneously, or of 1/10 c.c. intradermally, produces no reaction. Evidently diphtheria toxin possesses a marked affinity for the skin and subcutaneous tissues of the guinea pig and practically none at all for those of the rat. The authors find that, besides this difference in natural immunity between the two animals, there is a striking difference in the way in which they respond to artificial immunization. A course of five injections of antitoxin rendered a series of a dozen guinea pigs so immune that they were able to withstand more than 10,000 lethal doses of toxin, and in their serum sufficient antitoxin was present per cubic centimetre to neutralize 10,000 lethal doses. On the other hand, a similar series of injections in rats was not successful in rendering the animals resistant to even three lethal doses, examination of their serum failed to demonstrate the presence of any antitoxin—that is to say, artificial immunization produces a high grade of immunity in naturally susceptible animals, due to the development of antitoxin, in naturally resistant animals it hardly increases the immunity at all, and no antitoxin is generated. The authors point out the analogy existing between the human infant and the rat, and the human child and the guinea pig. The infant is Schick negative, contains no antitoxin, and fails to respond to artificial immunization; the child is Schick positive and responds readily to artificial immunization with the production of antitoxin.

358. Latency of the Herpes Virus.

ACCORDING to P. GASTVIEL and J. REILLY (*Bull. Méd.*, July 25th and 28th, 1928, p. 839) some animals can survive in spite of being carriers of active herpes virus, the guinea pig, for instance, after inoculation of its cornea, develops a keratitis which is usually not followed by any nervous disturbance, but if the animal is killed the presence of the herpes virus in its brain can be shown by inoculation of the cornea of another guinea pig. The herpes virus may therefore remain latent in an organ without giving rise to symptoms. Attempts to resuscitate the virus by producing an anaphylactic shock with injection of human or animal serum failed. On the other hand, the introduction of pneumococci into one rabbit which had just recovered from paralysis of the left lower limb following inoculation of herpes virus, and lumbar puncture of another which had just recovered from herpetic paraplegia, was followed by a return of the paralysis and death. Although they do not maintain that these observations entirely resemble those met with in clinical medicine, the authors hold that it may sometimes be possible to reproduce in animals the essential features of herpetic infection in man and to effect its resuscitation. This is manifested by the appearance of encephalitic symptoms in animals which are carriers of a latent virus.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine

329 Spontaneous Subcutaneous Emphysema in Laryngeal Diphtheria

J D ROLLESTON (*Brit Journ Child Dis*, July-September, 1928, p 185), who records an illustrative case, remarks that while subcutaneous emphysema is a well recognized complication of tracheotomy and occasionally occurs after intubation, it is a very rare occurrence in diphtheria apart from surgical intervention. Rolleston's patient was a girl, aged 6 who was admitted to hospital with severe faucial and laryngeal diphtheria. In spite of large doses of anti-toxin the dyspnoea increased and subcutaneous emphysema appeared on the neck, this spread upwards in the face and downwards to the costal margin. Considerable relief followed tracheotomy, but the emphysema lasted for eleven days, after which complete recovery followed. This is the first example of non-surgical emphysema which Rolleston has seen in more than twenty seven years of fever hospital experience. No mention is to be found of the complication of diphtheria in textbooks of general medicine or infectious diseases or in monographs on diphtheria, six cases, however, have been reported in periodical literature by Sachse, Senator, von Torday, Fahre, Pineau and Sharman and D'Estorzo respectively. The probable explanation of the condition is that as the result of dyspnoea pulmonary emphysema occurs, and vesicles on the surface of the lung rupture, air passes into the hilum of the lung, and so into the mediastinum and neck.

330 Bronchopulmonary Mycosis

J M DIAZ (*La med Ibera*, September 29th, 1928, p 272), who reports three illustrative cases in men aged from 22 to 30, states that the symptoms of bronchopulmonary mycosis are usually those of other more frequent infectious which are localized in the bronchi, lungs, or pleura. The only characteristic feature of the condition is its course, which may be described as a chronic process generally commencing in the bronchi, with a succession of subacute attacks of pulmonary inflammation and a tendency to the formation of nodules, necrosis, and sclerosis of the connective tissue. The clinical picture is that of bronchitis, bronchiectasis, bronchopneumonia, pneumonia, pulmonary abscess, and even gangrene and pleurisy, the course of which depends on the nature of the soil, individual reactions, or association with other micro-organisms. Owing to its chronic course it is most frequently diagnosed as pulmonary tuberculosis, especially when it is primary and assumes the form of millary dissemination, or when the nodules break down and form cavities. The error is most likely to be made when no fungus is found in the sputum, or only the tubercle bacillus when the two conditions are associated. Sometimes the disease may escape notice and not be discovered until the necropsy. The clinical diagnosis may be supported by the pre-existence of lesions of the skin (nodules, ulcers, and fistulae), mucous membranes (necroses and patches like thrush), or bones, especially if the pus contains granular concretions, or if in the absence of external lesions these granules are found in the sputum, particularly when this is tinged with blood or there is haemoptysis. In such cases Sabouraud's or Kanil's media should be inoculated with the sputum. Treatment consists in the administration of potassium iodide, or, if that fails, intrabronchial injection of lipiodol may be tried.

331 The Practicability of Antirachitic Prophylaxis

RIETSCHEL, SZEGÖ, and GERTRUD PRINKE (*Med Klinik*, August 31st, 1928, p 1343) discuss a simple and inexpensive method of preventing rickets which would not necessitate medical supervision or the prescription of drugs. Through the discovery of antirachitic substances, such as ergosterin, activated by irradiation, the treatment and prophylaxis of rickets have made a great advance. There are two practicable methods. The first is the administration of antirachitic substances in a 1 per cent oily solution, which may be administered in an emulsion, mixed with milk at the central milk depots of large towns. The flavour of the milk is not altered, and the mixture will be found to contain increased quantities of antirachitic substances which are chemically stable and unaffected by heat. The second method is to treat milk with ultra violet rays and thus to increase the content of antirachitic substances. The milk so treated, however,

has a rancid taste, and the employment of the mercury vapour lamp produces chemical and physical changes in it. Some deaths have been reported as following the administration of this irradiated milk. The authors describe a method of irradiating milk by means of a quartz lamp in an atmosphere of carbon dioxide. The milk is forced under compressed carbon dioxide through three "coils," each having a depth of 1 mm (1/25 inch) and covered by a plate of rock crystal. The milk flows slowly through the coils and is thus exposed to intensive irradiation by the quartz lamp. The apparatus is water cooled in order to prevent heating of the milk. During last winter the authors gave milk treated thus to a series of rachitic infants, and they also tested the practicability of the method in rats and guinea pigs. They confirm previous observations that the antirachitic content of the milk is increased and that thus experimental rickets in rats as well as infantile rickets can be cured. This method is said to be absolutely safe for animals and children. They add that such experiments are possible only in winter and spring, since in summer and autumn there is a natural tendency to spontaneous cure of rickets.

332 Vincent's Angina

V JEJINEK (*Acta Oto Laryngologica*, vol XI, Fasc 4, p 533) discusses three theories as to the etiology of Vincent's angina. The first is that it is due to vitamin deficiency, but against this view is the fact that the condition occurs in well-nourished troops on a liberal and varied diet, and attacks one regiment where another escapes though on identical rations. The second theory is that it is an infection set up by the eruption of the molar. Jejinek has observed that it usually occurs in some position other than that of proximity to the last molar, and he can see no connexion between the two phenomena. The third theory is that the condition is due to a specific infection by the spirochaete of Plant Vincent and the *Bacillus fusiformis*. The organisms are consistently found in the condition, its infectivity is shown by the way it spreads through a regiment of young healthy soldiers and by the way in which secondary infection occurs, especially on the fingers. Surgeons in attendance, oracles, and other patients in the same ward all tend to be infected, but other regiments in the same garrison or division often escape altogether. The author considers that the spirochaete is the really specific organism and originates the inflammation, while the bacillus acts as a parasite and continues the ulcerative process. The author's method of treatment consists of applying an ethyl chloride spray to the affected parts, protecting healthy tissue, and especially the teeth, with wool, India rubber, or in some cases with his own or an assistant's finger. Alternatively, and especially for ulcers of the tongue, he sprays ethyl chloride on to a pledget of cotton wool allows it to freeze, and then applies it to the ulcer. He sometimes substitutes a piece of ice for this pledget. Gargles of potassium chlorate or permanganate, and later hydrogen peroxide, are employed, and after the ulcers are healed the mouth is rigorously cleansed, with the removal of tartar and dental caries. The treatment is not at all painful, and may be repeated several times.

Surgery.

333. Traumatic Prostatic Backache.

L R BOIES (*Minnesota Med*, September, 1928, p 576) refers to the common occurrence of prolonged disability following comparatively trivial injury to the back, he believes that conditions frequently diagnosed as "neurasthenia," "neuritis," and "rheumatism" are often due to focal infections of the teeth, tonsils, or sinuses. The gall bladder or appendix may be regarded as the source of the disability, but chronic prostatitis is also a very common cause of such backache. One writer stated that 30 per cent of men have true prostatic hypertrophy, and 60 per cent have chronic prostatitis. Boies thinks this an extreme view, but adds that prostatitis and vesiculitis are not always venereal in origin. In chronic cases gonococci are rarely found, the principal organisms are *B. coli* and *Staphylococcus albus*, but in an equal proportion the expressed secretions are sterile. Boies reports ten cases of men, whose ages ranged from 23 to 49, who were seen within a period of two years, only one patient admitted having had gonorrhoea, all had been injured by falls or strains. In every case the prostate was inflamed and usually

very tender, the expressed secretions generally contained much pus. Boles suggests that the haematocho is a referred pain, due to imperfect drainage of the gland and to fibrositis, while a metastatic prostatic infection may occur, and there may be lumbosacral arthritis in some cases. The attitude which must be assumed in standing or walking increases muscular back strain. The author is convinced that in each case the prostatic disease was the important factor in the subjective complaints, and concludes that rectal examination should be a routine procedure, if any focal infection is suspected, microscopic examination of the prostatic and vesicular secretions is imperative. He adds that the absence of objective enlargement or of symptoms does not exclude the possibility of prostatic focal infection, and maintains that no orthopaedic procedure is justifiable in back injuries with obscure objective findings so long as there is evidence of prostatic infection.

384.

Tuberculous Synovitis

S. P. VASQUEZ and J. M. M. AREÑOS (*La med Ibera*, September 8th, 1928, p. 209), who record 21 illustrative cases with skiagrams, maintain the existence of a primary tuberculous synovitis. Trauma is the most frequent cause, being found in 75 per cent of the authors' foot cases. The symptoms of tuberculous synovitis may be divided into two groups—namely, a hydrarthrotic form and a fungating form. The hydrarthrotic form develops more rapidly, is associated with a dull pain, worse at night, limited movement is possible, muscular atrophy is slower than in the fungating form, regional adenopathy is slight, and contracture, though present, is not intense. Absorption of the fluid may occur, or the synovial membrane may become enlarged and have sequesterous abscesses. In the fungating form, which is of slower development, the pain and muscular atrophy are more intense and the limitation of movement and regional adenopathy are more marked than in the first form. Finally, there is suppuration with the formation of a fistula. The best mode of treatment is rest and improvement of the circulation, such as Bier's hyperaemia, so as to favour absorption of the effusion. Sympathectomy and puncture of the epiphysis are useful when the disease is limited to the synovial membrane, but bad when osseous lesions are present. Excellent results may be obtained by methods of revision, such as Scott's dressing or the cauter, accompanied by rest.

385

Surgery of the Pituitary Body

C. H. FRAZIER (*Annals of Surgery*, July, 1928, p. 1) points out that the peculiar relation of the pituitary body to the optic chiasma and nerves makes its surgery altogether different from that of cerebral or cerebellar tumours, the primary purpose in the former being to save vision, in the latter to save life. Of the two avenues of approach, the transfrontal has latterly been adopted in preference to the transphenoidal, since although the latter route is less hazardous, symptoms frequently recur, moreover, the capsule cannot be removed after evacuation, so that when it is firm and unyielding the effects of pressure on the optic chiasma may be only temporarily relieved. Local anaesthesia is preferred by Frazier to ether inhalation, since under the latter the intracranial pressure is greater, access to the base of the brain can only be obtained by elevating the brain mass, and this is only possible when there is a minimum intracranial pressure. In a few instances there was an unexplained fall in blood pressure, with collapse, and it was found that this fall did not occur when the lesion was approached from an angle along the greater wing of the sphenoid, the retro-orbitals being to one side and not pressing upon structures directly overlying the pituitary region. Since this lateral approach may render the lesion on the side opposite the flap less accessible, the propriety of a bilateral approach by a two-stage operation is considered, and a case is reported in which this was tried with excellent results, three months elapsing between the stages. Frazier adds that undue traction upon the capsule must be avoided as being likely to cause an alarming fall in blood pressure, the capsule should be resected piecemeal, and because of the attendant risks every step must be executed with the greatest delicacy and with a minimum of force.

386

Bladder Calculi in Young Children

J. WELFIELD (*Urol and Cut Rev*, August, 1928, p. 493), who records a case in a boy aged 10 states that calculi in the urinary tract occurs in early life to a much greater extent than is commonly supposed. Although urinary lithiasis is believed to originate in the kidney, calculi are more frequently found in the bladder, where they attain a relatively large size before symptoms suggest their presence. Vesical calculi are common in young children in Eastern Europe, in North America and in the northern part of South America. In some countries, such as France, vesical calculi in young children

are rare. About 95 per cent of bladder calculi found in early life occur in males, the majority being detected at or near the age of 5, they are not usually primary in the bladder, but originate in the kidney. Simple calculi are generally of uric acid origin, and about 50 per cent of bladder calculi are of this kind. Composite calculi contain a uric acid nucleus with urates and oxalates, upon which phosphates or ammonium-magnesium layers are superimposed when cystitis is present. Usually the calculus is single in a child's bladder, but multiple calculi are found in about 2 per cent. The ordinary symptoms are pollakiuria, nocturnal enuresis, interruption of the jet of urine, and a sensation of tickling in the glans. Cystitis is fairly common, especially in the advanced stages. Pyuria was present in 48 per cent of the cases of vesical calculi reported by Thomas and Tanner. The diagnosis is mostly established by x-ray examination. The prognosis depends on whether infection is present or not. Treatment consists in suprapubic incision, cystostomy, and removal of the calculus.

Therapeutics.

367

Sodium Citrate in Haemophilia.

E. PALMIERI (*Il Policlinico*, Sez. Prat., September 24th, 1928, p. 1817) reviews the literature and records an illustrative case in which sodium citrate acted as a haemostatic in haemophilia when all other measures had failed. He states that it is important that the solution should be as fresh as possible, the fluid should be injected very slowly by the intravenous route, in which case no complications of any kind are likely to occur. Palmieri's patient was a soldier who after operation for a left varicocele under local anaesthesia with novocain, developed an extensive haematoma of the scrotum, perineum, and pubic region. The wound was reopened and a large quantity of partly coagulated dark blood evacuated. In spite of an intravenous injection of coagulin, the subcutaneous administration of normal saline solution, and intramuscular injections of calcium chloride and ergot, the condition became worse. Finally 30 c.c. of a sterile 20 per cent solution of sodium citrate was introduced slowly into the vein of the left arm, and recovery followed. On inquiry the patient stated that he was subject to frequent epistaxis and bled profusely after slight injuries.

388.

Arsenic in Chorea.

In a series of carefully controlled cases S. GRAHAM (*Arch Dis in Childhood*, August, 1928, p. 206) found that the course of chorea did not appear to be influenced by treatment with arsenic. He thinks that any improvement shown should be attributed to the toxic effect of the arsenic, since it is not in proportion to the amount of arsenic given. The intravenous administration of arsenic has no advantages over other methods of treatment. Simple rest in bed and freedom from emotional disturbances will, he adds, usually cause a disappearance of chorea in four or five weeks, but the administration of sodium salicylate is recommended in the hope that it may favourably affect the rheumatism. None of the children so treated displayed any intolerance, the salt was given in 10- to 20-grain doses three times a day, with twice the amount of sodium bicarbonate five times daily. In patients treated with arsenic, neokharalvan was given at four-day intervals, the total average amount injected being 2.15 grams. In four cases toxic symptoms appeared, apparently due to idiosyncrasy. In patients treated with arsenic by the mouth the average total amount given was 11.5 drachms of liquor arsenicalis; two children showed signs of intolerance, which disappeared when the drug was stopped.

369

Resuscitation by Intracardiac Injections of Adrenaline.

J. NORDENTOF (*Ugeskrift for Læger*, August 2nd, 1928, p. 741) has given intracardiac injections of adrenaline in three cases, in two of which the heart was made to beat again, but only momentarily, the condition of the patient being incompatible with life. The third case was that of a man, aged 81, on whom suprapubic cystostomy was performed under lumbar anaesthesia for enlargement of the prostate. Towards the end of the operation he collapsed completely, pulse and respiration ceasing. Through a needle inserted in the fourth intercostal space, along the upper border of the fifth rib, and passing obliquely upwards and inwards, 1 c.c. of a 0.1 per cent solution of adrenaline was injected. Within about two seconds very violent heart beats began, the face became flushed instead of grey, and the respiration returned being natural and deep. After making an uneventful recovery during the following fourteen days he suddenly collapsed and died. From a study of the literature the author concludes that recovery may be

affected by this means even after the heart has ceased to beat for ten minutes, recoveries after a longer interval are very rare, and there is no record of a successful resuscitation after an interval of twenty minutes. Until 1925 about thirty cases of intubation with intracardiac injections of adrenalin in human beings had been recorded, permanent successes being achieved in about half this number. The survivors showed no permanent ill effects, and even in the cases which terminated fatally necropsies brought to light no trace of the injection, but in some cases the injections were followed by transitory disturbances of the nervous system, such as epileptiform twitchings. Of all the drugs used for this purpose, including camphor, atropine, and extracts of the pituitary body, adrenalin would seem to be by far the most effective.

370 Treatment of Haemorrhoids with Injections

V. MEISEN (*Ugeskrift for Læger*, June 7th, 1928, p. 523) recommends the injection treatment of haemorrhoids on the basis of one hundred cases, only one of which was complicated by necrosis. In seventy-two cases the patients were men, and in twenty-eight, women. The average number of injections given to each patient was three, with an interval of a few days between each. In eleven cases one single injection sufficed, and the greatest number of injections in a single case was thirteen. An acute attack of haemorrhoids, whether it occurs as the first manifestation of this disease or as an exacerbation of a chronic condition, is considered absolutely unsuited for treatment by injections. After the internal haemorrhoids have been brought to the surface, tincture of iodine is applied, 0.5 c.c. of novocain is injected through a hypodermic needle, followed very soon afterwards by the solution, the composition of which the author has changed from time to time. At first he used a 20 per cent solution of sodium salicylate, only in one case giving over 1 c.c. Later, and in most of his cases, he gave an almost neutral solution of guanine and urethane, according to the following formula: chlor. chl. 0.50, ethylurethane 0.25, aqua dest. ad 2 c.c. Still more recently he has substituted for this solution one containing 50 per cent of grape sugar. This may be somewhat less effective than sodium salicylate, but it has the advantage of causing no pain and not giving rise to necrosis. For x-ray work the author has used a 20 per cent solution of strontium bromide, which is also an effective thrombotic agent. When he first began this treatment he used to send his patients home with a prescription for opium suppositories, but only in the case in which necrosis supervened was there any need for them. Indeed, many of the patients experienced relief after the injection in spite of an oedematous reaction. The risks of embolism and infection are said to be negligible, and those of necrosis small. The author does not, however, advise general practitioners to attempt this treatment themselves, for it requires a good deal of dexterity, and may have necrosis as a sequel. It should be noted in this connection that the structures concerned are much more delicate and easily injured than are varicose veins of the legs. But with these reservations, and after three years' experience, the author recommends this treatment because it is ambulatory and painless, and does not necessitate a general anaesthetic. He cannot yet calculate the chances of a recurrence, but he does not think they are considerable.

Dermatology.

371 Systemic Blastomycosis

D. C. SMITH, H. O. TURNER, and E. S. SANDERSON (*Brit. Journ. of Derm. and Syph.*, August-September, 1928, p. 344) report a fatal case of systemic blastomycosis which occurred in a man, aged 42 who complained of cough, skin eruption, and swelling of the extremities. Four months previously a small red tender nodule developed on the bridge of the nose, finally discharging blood stained pus. Similar nodules developed later on the extremities and over the entire body and followed the same course, while the patient's general condition progressed downwards, with headaches, malaise and loss of weight. He developed a troublesome cough, with purulent expectoration, but had no chills or night sweats, and his appetite remained good. Solid and fluctuant abscesses in the corium and subcutaneous tissues, varying in size from 1 to 10 cm. in diameter, were generalized over the body, with communicating sinuses discharging thick, tenacious, greenish yellow pus. In addition there were many scattered granulomatous lesions, and ulcerated areas were present in the mouth and external auditory canals. A ray examination showed lesions resembling military tuberculosis in the right lung. Wassermann tests and blood culture examinations were negative, but the sputum and pus from the abscesses showed numerous blastomycetes. Microscopic

examination of the pus showed typical double contoured "round" forms, readily cultivated, and reproducing chiefly in the mycelial form. No harmful effect resulted from inoculations in rabbits, guinea pigs, or mice. Both morphologically and culturally the organism from this case presented characteristics similar to the majority of strains of blastomycosis previously reported. While it would appear that practically every structure of the body can become involved in the systemic infections, the skin and lungs are the organs of predilection for attack, and form the principal portals of infection. Since it may be reasonably assumed that dissemination from the cutaneous lesions rarely occurs, the primary focus of infection in systemic cases seems to be most frequently through the bronchi, whence the organisms may spread through the blood and lymph streams, producing multiple metastatic foci. Treatment with large doses of potassium iodide is recommended, and the possibility of inhibiting the growth of the blastomycetes by dilute concentrations of gentian violet has recently been suggested, the proper ventilation, lighting and drainage of houses and workshops are important aids in prevention.

372 Etiology and Treatment of Pityriasis Rosea.

H. H. HAZEN (*Journ. Amer. Med. Assoc.*, September 1st, 1928, p. 645) concludes that pityriasis rosea is probably due to an infection which enters either through the tonsils or through other lymphoid structures of the throat. He remarks that this disease usually commences with slight soreness of the throat, and that, a day or two later, one large lesion appears on the hand, body, or limbs. About five days afterwards an erythematous rash develops over the trunk, and a week subsequently lesions are found on the limbs. The disease is distinctly self limited, lasting from three to seven weeks, and is rather analogous to German measles. It is not uncommon and tends to occur in epidemics though more than one case is rarely seen in a household. Hazen has reviewed eighty-five consecutive cases, and reports that in forty-six of those, in which the notes were complete, the throat condition was satisfactory in only two instances. One patient, who had had three attacks, showed marked follicular changes in each one. The employment of ultra violet rays cut short the disease, and the author recommends the administration of an experimental dose over the entire body first, this being followed in from five to seven days by a second dose just sufficient to cause slight redness.

373 Sarcoid and Related Lesions.

W. H. GOECKERMAN (*Arch. Derm. and Syph.*, August, 1928, p. 237) reports seventeen cases of sarcoid and related lesions, and reviews the recent literature in this connexion. He maintains that sharp differentiation is practically impossible in some cases of the sarcoids of Boeck and Darier-Roussay, lupus pernio, erythema induratum, and nodular tuberculosis of the subcutis, though in all these lesions the originating factor is probably the tubercle bacillus. He thinks that the lesions in other tissues which are often associated with these conditions should be recognized as constituting a syndrome with cutaneous manifestations, and he suggests that, by taking into consideration these associated lesions, a better classification might be devised. The microscopic characteristics are, in Goeckerman's opinion, insufficiently specific to aid in differentiation, they are even to be found in some cutaneous lesions of syphilis and leprosy. Arsenic has not been found to be a specific in these sarcoids or related conditions.

Obstetrics and Gynaecology.

374 Pregnancy associated with Fibroma.

R. D. ERNST (*Brunelles Medical*, September 9th, 1928, p. 1458) reports a case of pregnancy which was complicated by a large fibroma in the left ligament. An additional difficulty in making the diagnosis was due to the menses persisting up to the fifth month. At four and a half months, when the patient was examined, a soft tumour was found in the abdomen, this extended up to three fingerbreadths above the umbilicus and was much deviated to the right. It was concluded that this was the gravid uterus. On the left side a hard tumour was felt, separated from the other one by a groove, and displacing into the left iliac fossa, this tumour extended to three fingerbreadths below the umbilicus. The subjective symptoms being corroborative of pregnancy in spite of the continuance of the menses a diagnosis was made of a four and a half months gravid uterus with a fibroid tumour in the left ligament, and confirmed by a radiogram. Expectant treatment was adopted and the patient was seen at weekly intervals during the remainder of her pregnancy. She remained in good health, with absence of any grave

manifestations until, towards the end of the time, dyspnoea became troublesome. A second radiogram, taken at thirty-two weeks, showed that the foetus was nearing full growth. Two weeks later the patient had a few mild uterine contractions. These yielded to treatment, and Caesarean section was performed a week later. A living child was delivered and subtotal hysterectomy was performed. The weight of the child and the total tumour mass removed was 15½ lb. In addition to the large fibroid tumour, which was adherent to the left uterine wall, there were multiple subserous fibromata. The post-operative course was normal and the patient made a good recovery, but the child died from broncho pneumonia on the twenty-fourth day.

375 Rapid Termination of Pregnancy

P. DELMAS (*Méd. Wcst.*, September 8th, 1928, p. 1349) describes a method of delivery under spinal anaesthesia useful in cases when quick emptying of the uterus is essential. He removes by lumbar puncture 10 to 15 c.c. of cerebrospinal fluid, of which 5 c.c. are used to dissolve 10 grams of a sterile neuro-cain preparation and are re-injected. The patient is then put in the lithotomy position prepared for operation, the bladder is emptied by catheter. The uterus is then opened up as follows. The right hand is introduced into the vagina, and the index finger is passed into the cervix and lower uterine segment, its distal phalanges are then bent and the lower uterine segment massaged until it is soft enough to admit the middle and eventually all four fingers. After a pause the whole hand is passed into the uterus, it pushes the hand up and works to and fro and then up and down until all resistance is overcome and dilatation is complete. The child is extracted by rupturing the membranes if this has not already occurred, performing internal version, and delivering. If the retraction of the uterus makes version difficult, forceps may be applied. As soon as the uterus is firmly contracted a vaginal douche is given and the placenta is allowed time for spontaneous expulsion. As prophylaxis an intravenous injection of Lingel's solution and a subcutaneous injection of 0.12 gram of sulfarsenol are given. All the forty cases of Delmas were successfully treated thus, the only maternal death being due to haemorrhage from a general placenta praevia. The author adds that the procedure is very quick, the complete emptying of the uterus taking on an average fifteen minutes. It can be performed with safety only in a completely undamaged uterus, with no old scars, cervical cancer, or infiltration tumours. It is useful during pregnancy—in the pre-eclamptic state, discrepancy between the pelvis and foetal head, and ante-partum haemorrhage, during labour—in eclampsia, pathological conditions of heart and lungs, or, if the foetal condition requires it, as in the case of a prolapsed cord. It can only be undertaken by a really skilful and experienced operator, and in such hands it is a useful method of speedy delivery.

376 Epidural Anaesthesia in Obstetrics

The various disadvantages encountered in the employment of spinal anaesthesia have led P. DALEAS and A. GALEY GASPAROU (*Gynéc. et Obstet.*, July, 1928, p. 37) to advocate epidural anaesthesia, which combines harmlessness with an action sufficient for all interventions by way of the natural passages. In this form of anaesthesia the authors prefer the sacral method of Cathelin, the technique of which is described in some detail. The first step in the procedure is to define the sacral hiatus, a space formed by the non-coalescence of the posterior arcs of one or more vertebrae, and the base of which is always found at the lower extremity of the sacrum. The guiding marks to this space are the spinous apophysis of the last coalesced sacral vertebra, which marks the upper angle of the hiatus, and laterally the twin tubercles which define the posterior arcs of the non-coalesced vertebra or vertebrae. A needle penetrating on the median line between or immediately below these points is certain to enter the hiatus. The anaesthetic employed is a 2 per cent solution of novocain in isotonic serum which also contains sodium chlorid and bicarbonate, the latter aiding in producing a good anaesthesia. As novocain rapidly loses its anaesthetic power in alkaline solutions, the mixture must be made at the time of the injection, the addition of adrenaline has been found to be of no advantage. This method produces a complete anaesthesia of both the superficial and deep perineum and of all the tissues contained in the true pelvis. Possessing no action on the motor centres of the uterus, the solution does not affect uterine tonicity and contractions, and causes no complications in delivery. Epidural anaesthesia is said to be the method of choice in all obstetrical and gynaecological operations involving the vulva, perineum, vagina, and cervix. Its use is excluded in such operations as phlebectomies and Caesarean sections. It does not interrupt or retard the progress of labour, and does not prevent the use of another anaesthetic should such necessity arise. Having no ill effects on the

general condition, it is not contraindicated by exhaustion, shock, intoxication, or anaemia of the patient, and the only contraindications to its use are partial or total contraction of the uterus, and a degree of obesity in which the thickness of the subcutaneous fat renders epidural puncture impossible.

Pathology.

377 Chloroform and the Hepatic Function.

S. M. ROSENTHAL and W. BOURNE (*Anesthesia and Analgesia*, September-October, 1928, p. 276) state that anaesthetics modify physiological processes, and that the change they produce on the liver is only a reflection of widespread depression of the cell activity. In order to ascertain their hepatic effect the authors have made a series of experiments on dogs with various anaesthetics, the tests employed, based on pigment metabolism, were the bilirubin concentration in the blood and the urobilinogen excretion in the urine. Brief periods of chloroform anaesthesia were found to produce immediate and delayed toxic effects on the liver, half an hour of chloroform administration caused injury which required eight days for functional recovery, while after two hours of anaesthesia six weeks elapsed before the return to normal. Functional disturbances could be demonstrated with the bromsulphalein test long after the pigment metabolism had recovered. Ether produced a definite but transient impairment of function, recovery being usually complete in twenty-four hours. Nitrous oxide and ethylene administered through a mask did not cause any change in the bromsulphalein test for hepatic function or any disturbance of pigment metabolism, but if given in a closed chamber with poor oxygenation both immediate and delayed toxic effects on the liver were caused. Cyanosis in itself increased the toxicity of anaesthetics on the liver. Large doses of morphine give rise to considerable depression of function, with complete recovery in twenty-four hours. The experiments seemed to indicate ethylene as the anaesthetic of choice for operation in severe liver disease.

378 The Mechanism of Recovery from Lobar Pneumonia.

R. H. P. SIA, O. H. ROBERTSON, and S. T. WOO (*Journ. Exper. Med.*, October, 1928, p. 513) have studied the time of appearance of immune bodies in the serum of patients with lobar pneumonia. The pneumococcal power—that is, the power of the serum to destroy pneumococci—was tested by adding decreasing amounts of the patient's serum to rabbit serum leucocyte mixtures containing small numbers of highly virulent pneumococci. Since these mixtures by themselves have no inhibitory effect on the growth of pneumococci, any pneumococcal effect that occurs must be due to the added test serum. Estimations were likewise made of the agglutinating and opsonic powers of the patient's serum, as also of its power of protecting mice injected with virulent pneumococci. In all, seventeen patients were studied, of these, five were infected with pneumococcus Type 1, six with Type 2, two with Type 2 atypical, and four with Group 4. Sixteen of the patients recovered, and one died. The results showed that immune bodies first became demonstrable in the serum at about the time that the temperature began to fall, whether this occurred by crisis or lysis. In only one case was evidence of antibody production found before the commencement of defervescence, and then only a few hours beforehand. These results applied to the patients that recovered. In the patient that died no pneumococcal powers were demonstrated in the serum, unfortunately, the other antibodies were not tested for. The observations made in this paper are practically identical with previous findings in experimental pneumonia of cats, and lead the authors to conclude that the development of serum immune bodies at the time of crisis must be regarded as an event of considerable significance. How far the antibodies are responsible for the crisis it is impossible as yet to say.

379 Levulose Tolerance in Rheumatism.

R. T. CHADWICK (*Arch. Dis. in Childhood*, August, 1928, p. 179) describes investigations in which the levulose tolerance test was performed on healthy children and also on those with active disease, especially rheumatism. The administration of levulose was found to have little or no effect on the blood sugar in the healthy children and on those with either simple chorea or who were convalescent from rheumatism. In the child with active rheumatism whether the heart was affected or not, and in the choreic with heart affection, there was, however, an appreciable intolerance to levulose. The author concludes that this intolerance to levulose must be due to some toxic absorption from a focus of rheumatic infection.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine

380 Occupational Causes of Gastro Intestinal Disease

ACCORDING to T. LÖWY (*Med. Klin.*, September 7th, 1928, p. 1383) the acid gastric juice, in addition to its other functions, defends the intestinal tract against infection by ingested organisms and is also one of the regulators of the ionic balance in the blood stream during muscular exertion. During prolonged muscular work the alkali reserve of the blood plasma tends to fall and the secretion of acid gastric juice rises. Subsequently the blood alkali reserve increases again and the gastric secretion of hydrochloric acid diminishes. A feeling of fatigue is associated with disturbance of the ionic balance in the blood, and a diet rich in protein, such as the heavy manual worker instinctively demands, by stimulating acid gastric secretion, helps to restore the ionic balance in the blood to normal. Thus occupations causing disturbance of gastric secretion are of particular importance in determining the working power of the body. Though a congenital tendency to gastric and duodenal ulcer is now generally recognized to exist, chemical, mechanical, and traumatic factors play a part in the production of these lesions. Among mechanical factors Löwy mentions the swallowing of sharp particles of dust—by stonemasons and metal workers, for example. The alkali vapours swallowed by workers in candle, warfarn, and soap works tend to neutralize the gastric juice, and by diminishing its sterilizing powers facilitate the entry of pathogenic organisms into the intestine, where they give rise to catarrhs. The connexion between intestinal disorders and occupation is in some cases more direct—as for example, hernia, the atonic constipation of sedentary workers, and the constipation of the spastic type which is comparatively common amongst postmen, land workers, and others leading an active life, this last is best relieved by rest, antispasmodic drugs, and a diet containing a minimum of roughage.

381

Pulmonary Arteritis

M. WYBAUW (*Le Scalpel*, August 11th, 1928, p. 901) records two cases of pulmonary arteritis which show similar features. Both patients were women, aged respectively 42 and 25. The chief symptoms were dyspnoea and inability to work, both had coughs and sputum in which no tubercle bacilli could be found, some haematemesis and blood streaked expectoration, marked cyanosis and oedema, negative Wassermann reactions, and no rise of temperature. The first patient had chronic bronchitis; the second had been unable from an early age to play like other children, and had had some slight rheumatism. Cardiac examination by percussio and auscultation did not result in a satisfactory diagnosis. At necropsy the second patient showed especially a very dilated right ventricle and left auricle, and a narrow, funnel shaped mitral orifice, with mitral valves but no visible vegetations, by a microscopical examination, however, chronic inflammatory lesions were found. The valvular orifice of the pulmonary artery was dilated, and on its wall there were small raised yellowish white spots like those found in arteritis. The medium sized arteries were very thick and revealed changes characteristic of chronic endarteritis. The author concludes by stating that pulmonary arteritis, though rare, does exist, but is difficult to diagnose during life. It appears usually as a complication either of mitral disease, generally stenosis, or of chronic pulmonary trouble, such as bronchitis, tuberculosis, or emphysema. To these diseases certain characteristic features are added—namely, cyanosis, haemoptysis, increase in the pulmonary arch as measured by radiography, increase in bulk of the hila, and marked dilatation of the right ventricle, with right electrocardiographic predominance. The course of the disease is unfavourable and often rapid, cardiac drugs usually having only a temporary action.

382.

Panniculitis

H. A. CHRISTIAN (*Arch. Int. Med.*, September, 1928, p. 338) records a case of relapsing febrile nodular non suppurative panniculitis occurring in a single woman aged 25, who had ten recurring attacks in which subcutaneous lumps appeared chiefly on the arms and legs. These became flattened and attached to the skin, finally leaving a depression without suppuration, while the continuity of the skin remained unbroken. The attacks were accompanied by fever, nausea, vomiting, and muscle pain, the variations in temperature reaching a daily higher level, with a more gradual decrease. While the fever and relapses suggest that the condition may be a manifestation of undulant fever from

infection with organisms of the *M. melitensis* or *B. abortus* group, the cultures in this case were negative. As a result of the subcutaneous nodular inflammation necrosis of some of the fatty tissue occurs, and much of it becomes infiltrated with lymphoid and plasma cells. Macrophages take up fat in fine droplets, and a few foreign body giant cells appear. Atrophy of the nodules results, causing a depression in the contour of the skin without there having been any break in its continuity. Towards the end of convalescence from her tenth attack the patient developed acute appendicitis, for which she was operated upon without any resulting complications. The etiology is said to be unknown.

383 Intestinal Origin of some Acute Infections

A. GIOVANNARDI (*Bull. de Sci. Méd.*, July-August, 1928, p. 232) found that *B. typhosus*, *B. paratyphosus* B, and *B. anthracis*, when given by the mouth to normal rabbits, passed through the barrier formed by the gastric juice and reached the intestine directly. The passage of these organisms into the intestine occurred with considerable frequency and regularly when they were attached to green vegetables. They reached the intestine fairly quickly—namely, in one or two hours after food—and might remain there a considerable time. In some cases they were found in the mesenteric glands a few hours after they had been swallowed. While, however, the passage of *B. typhosus* or *B. paratyphosus* B through the stomach into the intestine occurred with considerable frequency, it was not proved that the organisms after this passage were the cause of disease. It may be supposed that under normal conditions the intestinal mucous membrane is not susceptible to this infection without the intervention of other factors. On the other hand, when an organism was virulent for the rabbit, such as *B. anthracis* was administered by the mouth in green vegetables infection and death from anthrax sometimes occurred.

384 Cisternal Puncture in Cerebro spinal Fever

ACCORDING to V. PALCSO (*Wien. Klin. Woch.*, August 16th, 1928, p. 1182) four cases of cerebro-spinal meningitis successfully treated by cisternal puncture have been recorded by Ayor, Nonne, and Hartwich (two cases) respectively. Palcsó now adds two more—in a man aged 22, and a woman, aged 41. The only disagreeable symptoms noted were severe headache, sweating, and vomiting, which occurred in one of the patients and lasted about twenty minutes. The method is relatively indicated in those cases in which lumbar puncture is also practicable, and absolutely indicated when lumbar puncture is ineffective—as, for example, when the fluid is purulent and sticky and enough cannot be evacuated, or there are any local lesions or deformities which interfere with the operation.

Surgery.

385. Enlargement of the Thymus Gland.

F. W. O'BRIEN (*New England Journ. Med.*, October 4th, 1928, p. 657) reviews the literature relating to the thymus gland, and concludes that the thymus has no secretion as such, though its involution in otherwise normal children at puberty suggests a definite relationship with the sex glands. He is believed that the thymus was not itself essential to life, though death by wasting followed the removal of this organ together with the spleen. Hammar suggested that the lymphocytes in the gland were necessary postulates for its functioning, and indicated an antitoxic activity, the thymus not being a transitory organ, but existing and functioning even until old age. Hyperplasia is relatively rare and is found chiefly after castration, and in Graves's disease, Addison's disease, myasthenia, aoromegaly, and the so-called "thymus death." Cases of the latter, with which alone O'Brien deals, can be divided into those with and those without symptoms. The existence of a symptom producing thymus is conceded, but opinions differ as to whether an enlarged thymus is a causal factor of sudden death. In radiographs an enlarged thymus casts a shadow larger than that of the great vessels. Mosher, Macmillan, and Motley report that of 2,344 children 7.5 per cent showed a positive thymus shadow that all the latter were successfully operated on after x-ray treatment of the mediastinum, and that no unexplained sudden death has occurred since this treatment was instituted. Similar experiences are reported by O'Brien in some 2,526 cases. Since there is no evidence that the

thymus is not an integral onasativo factor in sudden death, and as it is known that involution of this gland takes place rapidly and without harm following a ray or radium treatment, O'Brien believes that it is not only desirable, but necessary, till more exact knowledge shall warrant a contrary opinion, to prescribe radiation therapy for those children presenting a ray evidence of the "broadened mediastinal shadow" without symptoms, for whom general anaesthesia or surgery is contemplated.

Therapeutics.

339 Home Treatment of Common Urinary Complaints.

R CAMPBELL BEGG (*New Zealand Med Journ*, August, 1923, p 214) gives some suggestions for the management of certain urinary disorders by the general practitioner. In pyelitis after careful examination has excluded other possible troubles, alkalinization of the urine must be ensured, adequate doses of alkalis should be reinforced by a teaspoonful of sodium bicarbonate the last thing at night, and the patient should be given a book of red litmus papers and instructed to watch the reaction. If symptoms persist in spite of alkalinization, a special examination of urine for tubercle bacilli should always be made. In dysuria in women it should be remembered that cystocolo may be present in the absence of cervical protrusion. Acute gonococcal prostatitis is often seen, though gonococcal cystitis is rare. Frequent enemas of 4 ounces of hot water with 40 grains of antipyrin give great relief. The author believes that local anaesthesia is too seldom used in catheterization, and that much avoidable pain is caused. Cocaine is said to be the only sure drug, and to be quite safe if used in 1/2 per cent solution and injected slowly. One drachm should be introduced and pressed back through the posterior urethra while the meatus is compressed with the fingers. Another drachm should then be injected, and a clamp put on the meatus for a few minutes. Not more than 1.25 grains of cocaine should be used in all. Gum elastic catheters are, in the author's opinion, unsatisfactory. Eynard's silk web catheters can be helled, but this should be done in a towel, in which the catheters should be lifted out, there is risk of denting them with forceps while soft. In the dilatation of strictures Hilform metal or whalebone bougies should not be used since they easily damage the mucous membrane. Eynard's silk web Hilform bougies are made with a female screw for attachment to the male screw of a sound. If a ray examination fails to reveal a calculus after treatment of the acute pain at the onset it is probable that the stone may be too small to show, and in this case it will probably be expelled sooner or later, the patient is more likely to pass it if up and about than if confined to bed. In urinary retention due to prostatic enlargement the kidneys are usually already damaged. The bladder should never be completely emptied, and distension should be allowed to occur again before the patient can be voided. The author uses a condé silk web catheter. After partial emptying of the bladder a tube should be attached and carried over a chair at such a height that a slow drip of urine is ensured sufficient to keep pace with renal secretion, the catheter is kept in place pending more radical treatment.

390 The Gold Treatment of Pulmonary Tuberculosis.

A FARJON, P. MAZILLY, and P. LEFFEVRE (*Presses Méd*, September 26th, 1923, p 1218) believe that the accidents encountered during the use of sanocrysin in the treatment of pulmonary tuberculosis are due solely to the large doses employed. They found that, in smaller doses, patients undoubtedly benefited from its administration, the general health almost constantly improved, the cough and expectoration diminished with a disappearance of bacilli from the sputum, the weight increased, and the fever progressively lessened. It is pointed out that improvement, however slight, often raises the patient's morale—an important factor in treatment. The authors give at weekly intervals the following doses by intravenous injection: 0.05, 0.1, 0.15, 0.2, and 0.25 gram, they repeat the last dose until 2 grams have been administered. The injections are preferably given two hours after food. In order to avoid cumulative action, sanocrysin being but slowly eliminated by the kidneys, one and a half to two months are allowed to elapse between each series of treatments. The authors advise that, in certain susceptible cases, the cumulative dose should be only 0.01 to 0.025 gram, and the doses should not exceed 0.05 or 0.1 gram until it is ascertained that the preceding ones have been well tolerated. Even in small doses the injections may have certain effects, which, however, are very trivial and need not interrupt treatment. These are: pain and localized redness at the site of the injection at the time of the injection; slight malaise, vertigo, and sometimes nausea, which disappear in a few minutes; headache and lumbar pain and a slight rise of temperature of about half a degree. If the fever is prolonged, and albuminuria, cutaneous eruptions, or nervous or intestinal troubles arise treatment should be discontinued for a time. Haemoptysis was never noted, but, should this occur, treatment should be stopped for a short period. Sanocrysin is said to be of no benefit in acute tuberculosis, but only in the chronic febrile or subfebrile types. The authors have treated 46 such cases, with good results in 31. The drug is contraindicated

386 Surgical Treatment of Gall-stones

G LUTZOW HOLM (*Norsk Mag f Lægevid*, August, 1923, p 741) reports 180 operations for gall stones performed at the Rik's Hospital, Oslo, in the period 1910 to 1926. Cholecystectomy was the method of choice, and, when necessary, was associated with cholecystotomy and drainage of the hepatic duct. Cholecystotomy was performed only in exceptional circumstances, such as weakly patients. It was regarded as more dangerous to operate in the acute stage than in the interval between attacks. An operation, therefore, was only performed in acute cholecystitis when there was evidence of perforation or impending perforation. Not more than eight patients were operated on during an attack, and the rest were operated on one to two weeks after disappearance of the acute symptoms. Seven deaths occurred—a mortality of 3.9 per cent—the cause of death being peritonitis in 3, degeneration of the heart and liver in 2, cholemic haemorrhage in 1, and broncho pneumonia in 1. The peritoneal cavity was never closed primarily, but was usually treated with a ekgarot drain for six to eight days. The end results were investigated by inquiries sent to patients who had been operated on between 1910 and 1924. In about 90 per cent of the cases of cholecystectomy the results were good, while in the remaining 10 per cent pain and attacks of colic continued. Like most other operators, the author very rarely found calculi when another operation was performed but almost invariably encountered adhesions between the liver and bile ducts with the stomach, duodenum, and colon, which he concludes, should be regarded as the principal cause of the pain following operation. These symptoms obviously occurred in patients who had suffered from colic for many years, so that adhesions had probably formed long before operation. Early operation is, therefore, strongly to be recommended.

387 Chronic Infections of the Prostate and Seminal Vesicles

C H GARVIN (*Med Journ and Record*, September 5th, 1923, p 213) believes that chronic posterior urethritis and chronic prostatitis are clinically synonymous, and that in chronic prostatitis the seminal vesicles are always involved. Non-specific prostatitis and vesiculitis are much more common than is generally thought, the symptoms, clinical findings, and treatment differ but slightly from those due to the gonococcus. Acute anterior gonorrhoeal urethritis can be said to have extended to the prostate and vesicles whenever the discharge has persisted, in spite of treatment, for more than four weeks. Rectal examination of the prostate without microscopical examination of the expressed secretion is inadequate. Garvin adds that treatment must be continued until all evidence of infection has disappeared, and that massage, dilatation, and instillation will ultimately cure any case. A standard of cure which does not include urethroscopy and microscopical examination, with cultural examination of the expressed secretion of prostate and vesicles, is held to be incomplete.

388 Abdominal Adhesions.

W S BAINBRIDGE, whose results in the treatment of cases of abdominal adhesions by means of plastic surgery are reported by Haller (*Bull et Mém Soc Chir de Paris*, July 6th, 1928, p 609), attributes the condition to various causes. If it occurs before operation it may be due to tuberculous peritonitis, long standing ulceration of the intestinal tract, syphilis, affections of the biliary organs and ducts, or inflammation of other organs adjoining the peritoneum. When these adhesions occur with only slight symptoms medical treatment will often prove efficacious, but in more severe cases radical surgical intervention is necessary and sometimes a short-circuit is the most successful operation. Between the slight and the severe cases there exists a large group where the alimentary canal can be freed by means of simple plastic surgery. This must be conducted with great care at an early stage, the operation being performed quickly and the tissues handled very gently. Warm saline solution should be introduced into the intestines during the operation to prevent the formation of fresh adhesions. In the seven cases reported the results were good after simple operations such as liberation of folds, section, and peritonization, the patients remaining in excellent health several years after treatment.

in cases with renal or digestive complications, in cases of advanced cachexia with hectic temperature, and in tuberculous laryngitis

391 Serum Treatment of Typhoid Fever

K. REINTHALER (*Seuchenbekämpfung*, Heft 4, 1928, p. 241) states that, in spite of the numerous outbreaks of typhoid fever in recent years, serum treatment, which was first introduced by Chautoussou in 1907, has not been extensively employed. The author used Kraus's anti endotoxin serum in a recent epidemic in 43 cases and found that the course of the disease in patients treated with this serum was more favourable both as regards the severity of the attack and the duration of the febrile period, which was only seven to sixteen days, whereas the great majority of the untreated cases considerably exceeded this period. No undesirable reactions, such as rigors or collapse, were observed. The number of injections ranged from one to four at intervals of from two to six days, and the doses from 10 to 20 c cm. The author found that the serum had no effect in relapses. The mortality of 12.4 per cent, in spite of the use of serum, is due to the fact that the fatal cases presented symptoms of peritonitis on admission, which were confirmed by the necropsy, only one patient died of myocarditis.

Anaesthetics.

392. Open Ether Anaesthetization in India.

J. B. HANCE and J. PERSHAD (*Indian Med Gazette*, September, 1928, p. 512) seek to dispel the belief current in some quarters that open ether is a difficult and expensive method of anaesthesia in hot climates. Working under conditions where the theatre temperature is frequently in the neighbourhood of 90° to 100° F. they have found that open ether can be employed with greater safety than chloroform and at small average expense. Their method is to use Shipway's apparatus, keeping the ether container at an average temperature of 50° F. and a Schimmelbusch mask resting on a Gamgee tissue face piece. During induction the bellows are used at a rate of twice per second, and subsequently at a steady rate of once per second. With patients of temperate habits they find that full surgical anaesthesia can usually be obtained in seven minutes, a "concentrating" layer of Gamgee tissue being placed over the Schimmelbusch mask after the induction stage. Tabular lists are given of operations, showing the time of anaesthesia, the temperature of the theatre, and the amount of ether used. This ranges from an average of 9.4 oz for major abdominal operations lasting up to two hours, to one of 3 oz for operations for haemorrhoids lasting about twenty minutes. They add that induction with the Shipway apparatus should become simple with practice if the patient will breathe deeply but induction with a C.E. mixture may be found by some easier at first.

393. Spinal Anaesthesia

AFTER reviewing the work of numerous authorities, O. J. CURRIE and J. A. CURRIE (*Journal Med Assoc of South Africa*, August 25th, 1928, p. 440) observe that most of these writers agree that the three outstanding merits of spinal anaesthesia are the prevention of shock, the ease of operating, due to perfect relaxation, and the prevention of certain sequelae of general anaesthesia, such as pneumonia. Spinal anaesthesia effects a true anoxic association, cutting off the brain from peripheral stimuli, but, since the anaesthesia causes a definite fall in blood pressure the presence of marked shock before operation is a contraindication to its use, as is also a blood pressure lower than 100 mm of mercury. Gentle operating is desirable owing to the possible painfulness of traction on neighbouring unanaesthetized parts. Moynihan's "destructive psycho strain" is not so severe as might be expected, and suitable psychological management, together with the use of hyoscine and morphine as a pre anaesthetic, dispels the fears of all but the very nervous. A summarized report is given of 45 cases of spinal anaesthesia, in 14 of which one of the authors operated single handed, stovaine alone being used. In the remaining cases Jonnesco's formula (stovaine and strychnine) was employed, these being kept in separate ampoules and mixed at the time of injection. The solution is usually heavier than cerebrospinal fluid, does not gravitate so markedly as Barker's solution of stovaine alone, and diffuses upwards to a certain extent. On reaching the theca a small quantity of cerebrospinal fluid was allowed to escape, the latter was then drawn into the syringe and allowed to mix with the solution, and the injection was made slowly. The dose of stovaine has varied from 2.5 cg in children to 9.5 cg in adults, the usual being 7 to 8 cg. The anaesthesia generally extended to one inch above the umbilicus, in one case reaching the clavicles.

It lasted from thirty minutes to two hours (in one case), the usual duration being thirty to forty five minutes. No deaths due to the anaesthetic have occurred, and the chief complication has been headache in some instances. In one case a slight transient diplopia was noted. Strychnine is said to lessen the duration of anaesthesia, and Jonnesco has recommended the substitution of caffeine. This author and Desplas claim that by injecting caffeine instead of strychnine the incidence of headache is greatly diminished and its severity lessened. The present authors, while bearing in mind its limitations, are inclined to favour spinal anaesthesia, either alone or combined with general anaesthesia and hyoscine.

394. Local Anaesthesia in the Reduction of Fractures

O. O. RICE (*Journal Amer Med Assoc*, June 2nd, 1928, p. 1768), whose paper was the subject of an annotation in our issue of August 4th (p. 217), suggests that local anaesthesia for the reduction of fractures deserves more extensive use. The advantages of the method are its simplicity, no additional equipment or detailed anatomical knowledge being necessary, its applicability at any time, even when the stomach is full, the satisfactory muscular relaxation, and the negligible danger of infection. The anaesthetic recommended is a 1 per cent solution of procaine hydrochloride, this is injected between and around the fragments and into the surrounding muscles. The amount used ranged from 15 to 60 c cm, but the smaller dose was found to be fully as satisfactory, and did not obscure the landmarks so much. During the past year Rice has treated more than fifty cases of fractures of the lower arm by this method, and reports seven of these. The results were very gratifying in all except two instances, in which the procaine had been administered the day before. The author remarks that at the lower end of the forearm the radius is prismatic, and the boundaries of this prism are defined. In administering the anaesthetic the arm should first be cleansed with soap and water, sterilized with iodine and alcohol, a sterile towel is placed over the hand, and another over the arm. With an ordinary hypodermic needle an initial puncture is made one inch above the fracture, over the subcutaneous dorsal border of the radius, 2 c cm are injected between this point and one opposite the lateral border, where the second subcutaneous wheal is made. The small needle is then replaced by a long flexible one (2½ in. 26 gauge), and this is directed straight down to the dorsal border, the tissues being injected as it advances. It is then directed along the medial radial surface, infiltrations being made into or as close as possible to the periosteum, and continued until the interosseous membrane is entered. The direction of the needle is then changed without withdrawal, it is introduced opposite the already anaesthetized lateral border, and directed across the ventral surface of the radius. Thus the three surfaces of the prism are infiltrated. During infiltration extravasated blood from the fractured bone may well up into the syringe, if it is not encountered, the needle is directed forward toward the fracture until blood appears in the syringe. About 4 or 5 c cm are injected at this point so that the procaine may reach the broken ends of the bone and the endosteum. Thirty minutes is allowed for the anaesthesia to develop, and the fracture is then reduced by the usual methods. Procaine anaesthesia should not be employed in the presence of infection, in compound fractures, or when it has been given only a short time previously.

Obstetrics and Gynaecology.

395. Pregnancy after Ureteral Transplantation

C. W. EBERBACH and J. M. PIERCE (*Surg, Gynecol and Obstet*, October, 1928, p. 540) record a case of pregnancy successfully terminated by Caesarean section in a patient upon whom two years previously bilateral transplantation of the uterus into the sigmoid for exstrophy of the bladder had been performed. Through an oblique muscle incision the peritoneum is stripped from the pelvic wall and the ureter cut as near to the bladder as possible and its distal end tied. A loop of sigmoid is drawn through a 5 cm peritoneal incision and the proximal end of the ureter is implanted therein by the method described by Coffey and Mayo. About a centimetre of the bowel is allowed to remain exposed extraperitoneally and sealed off by suturing the peritoneum to the intestinal wall, thus preventing any pull on the ureter and as a pre caution in the event of leakage. Urine usually appears in the rectum at once, and in a fortnight the second stage can be performed. In the case recorded uneventful recovery followed and pregnancy ensued two years later. At full term the abdomen showed normal distension, with a wide, firm, low mid line scar marking the site of the exstrophied bladder. The umbilicus was absent, and the two lateral transplantation operation scars were well healed and showed no sign of hernia. Below the fibrous symphysis and

surrounded with dense scar tissue was the vagina, 5 cm in length, and admitting two fingers, the labia were widely parted, and there was a bony separation of four inches at the symphysis. Following Caesarean section and delivery of a 5½ lb female child convalescence was normal, and throughout the pregnancy there was never any sign of pyelitis or nephritis. From this and three other cases previously reported it would appear that uterine transplantation does not necessarily contraindicate pregnancy—a point of importance in cases where sphincter damage or vesico vaginal fistula necessitates such a procedure.

396. Impacted Calculus in the Female Urethra

T. S. KLOTS (*Nederl. Tijdschr. v. Geneesk.*, September 1st, 1928, p. 4217), who records an illustrative case, remarks that incarceration of calculus in the female urethra is a remarkably rare occurrence owing to the passage being so distensible. As a rule the incarceration takes place immediately behind the external meatus, but it is also possible in other situations. Usually the symptoms set in suddenly with severe pain in the urethra, followed by difficult or painful micturition, the passage of turbid and not infrequently bloody urine, and often a purulent or sanious urethral discharge. There is also a constant pain, especially during coitus or on sitting. If infectious supervenes, perineurethral abscesses may develop and burst into the vagina. Incontinence of urine may supervene as the result of stretching of the vesical sphincter or in incarceration of the calculus in the neck of the bladder. The obstruction to the escape of urine may give rise to cystitis, followed by involvement of the kidney through back pressure. The diagnosis is usually easy if the possibility of the condition is remembered. The calculus can usually be felt through the vagina or by the passage of a sound. It will rarely be necessary to use a urethroscope or to make an x-ray examination. Treatment, which consists in removal of the stone, is much easier than in the male subject, and external urethrotomy will rarely be needed. The calculus can usually be pressed out by the finger in the vagina, or by a Collin's forceps or blunt curette. Klotz's patient was a woman who had suffered for some months from intermittent left-sided renal colic, polyuria, and painful micturition. The urine showed many pus cells and red corpuscles, but no casts. A sound passed into the urethra encountered a stone just below the neck of the bladder. The calculus was then removed by a forceps for extracting foreign bodies from the nose, and complete recovery followed within a week.

397. Pyrexia from Necrobiosis of Myomata.

E. GODLEWSKI (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, July, 1928, p. 643) records three cases illustrating the difficulty in diagnosis of pyrexia accompanying red degeneration of an unsuspected uterine myoma. The first patient had suffered for eighteen months from feverish attacks lasting twenty to twenty-five days, with digestive disturbances and meteorism, the diagnoses had successively been made of influenza, paratyphoid fever, and Malta fever, the serum having a faintly positive reaction. In the second case fever lasting seven months was accompanied by dyspepsia, recurrent diarrhoea, subfebrile, and ascites, tuberculous peritonitis was suspected, and the symptoms improved with rest, but were aggravated by actinotherapy. The third patient, a three para aged 38, had had three years of ill health with menstrual irregularity, loss of weight and pyrexia, which were attributed to plenury, an exacerbation of symptoms after six weeks' amenorrhoea was treated for post-abortion infection. In each case removal of myomata containing necrobiotic foci led to cure. In these cases the percentage of blood urea was considerably increased before operation.

Pathology.

398. Surface Tension Measurements in Bacterial Differentiation

A. A. DAY and W. M. GIBBS (*Journ. Infect. Dis.*, August, 1928, p. 97) after reviewing a number of recent papers on the effect of surface tension depressants on the growth of bacteria, conclude that at present there is no adequate and undeniable proof that surface tension plays any part in bacterial development. Many results which appear to indicate the favourable or unfavourable action of decreasing the surface tension can be equally well ascribed to the chemical properties of the particular depressant employed. In order to avoid this latter difficulty the authors decided to use a number of different depressants, if the effect on growth was the same, whether the given decrease in surface tension was brought about by one substance or another, then it might be inferred that it was the surface tension that was responsible, if, on the other

hand, entirely different results were obtained, depending on the particular substance used, then it would seem as if the chemical properties of the substance were responsible. They employed eight strains of *Lactobacillus acidophilus* and twelve strains of *Lactobacillus bulgaricus*, those organisms were chosen because certain workers have stated that they can be separated on the basis of surface tension alterations. The depressants used were sodium oleate, sodium taurocholate, sodium ricinoleate, and coco nut, palmitic, and olive soaps. These were added to a lactose broth medium in such quantities as would afford a range in surface tension from about 27 to 40 dynes. The tubes were inoculated, incubated at 37° C., and the amount of growth estimated every forty-eight hours by measuring the hydrogen ion concentration of the culture. The results showed no difference between the two organisms. Both grew quite well at about 30 dynes when sodium oleate or sodium taurocholate was used, but neither grew when sodium ricinoleate was used. The latter soap, in fact, proved to be very toxic, coco nut soap was slightly less so. The growth of *L. acidophilus* seemed to be actually increased by the other soaps, but not sufficiently to afford a reliable means of differentiation from *L. bulgaricus*. The authors conclude that none of these soaps seem to act by altering the surface tension, it is rather their chemical action that appears important in affecting the growth of bacteria.

399. The Boltz Reaction

E. MELKERSSON (*Acta Med. Scand.*, September 6th, 1928, p. 119) discusses the acetic anhydride-sulphuric acid test discovered by Boltz, in which 0.33 c.cm. of concentrated acetic acid is added drop by drop to 1 c.cm. of cerebrospinal fluid in a test tube. The mixture is shaken and 0.8 c.cm. of concentrated sulphuric acid is added drop by drop, after which the mixture is shaken again, and five minutes later the mixture is examined against a white background. A lilac or reddish blue tint indicates a positive reaction, if the fluid is colourless or yellowish the reaction is negative. Boltz claimed that the reaction was positive in 100 per cent. of cases of paralytic dementia, and in the majority of cases of psychoses associated with cerebrospinal syphilis, the positive reaction is said to be more definite in advanced cases. But Boltz was not convinced that the reaction was specific in regard to syphilis. Other investigators have found the test positive in almost all cases of dementia paralytica, being almost as reliable as the Wassermann test in this condition. A negative reaction was found in almost all other mental diseases except a few cases of syphilis of the central nervous system. Melkersson thinks that these writers were too optimistic. He has employed the test in 102 males and 64 females, whose ages ranged from 16 to 73, age and sex do not appear to influence the results. Melkersson concludes that the Boltz reaction is independent of pressure and of the cellular content of the cerebrospinal fluid, it is in no sense comparable with Nernst's reaction and a feebly positive result does not indicate the existence of an organic nervous disease. He obtained a positive reaction in many organic nervous diseases of various types, and does not consider it specific for paralytic dementia or for cerebrospinal syphilis.

400. Cultivation of the Relapsing Fever Spirochaetes

M. LAPIDARI and HÉLÈNE SPARROW (*Arch. de l'Inst. Pasteur de Tunis*, September, 1928, p. 191) have succeeded in growing relapsing fever spirochaetes in Unger mann's medium, which consists of a 20 per cent. dilution of rabbit serum in Loel's solution. The medium is distributed into narrow tubes, each of which contains 1 c.cm. of coagulated egg white, the whole is covered with vaseline. They found that this medium was greatly improved by substituting Hartley's broth for Loel's solution, not only did the organisms grow better, but they retained their vitality for a longer time. Subcultures gave very irregular results. It was noticed that the growth depended very much on the particular phase of the culture that was used for seeding. As a rule, the younger the culture from which the inoculum was taken the more rapidly did development occur in subculture. On the other hand when an old culture was employed, no growth might be noticeable for some days, then, quite suddenly, spirochaetes started to develop. Sometimes an initial phase of growth was followed by a phase of decline, so that no organisms could be found in the culture; this was followed in its turn by a second phase of growth, during which spirochaetes were again abundant. The authors consider that these observations simulate *in vitro* the phenomenon of recurrence. O. Nicolle, they state, believes that the relapses in relapsing fever are due not to a periodic reaction of the patient, but to a specific biological property of the organism itself. These observations of alternate phases of growth and decline in artificial cultures lend some support to this view.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

401 Early Diagnosis of Pulmonary Tuberculosis.

BURKARD (*Wien Klin Woch*, September 20th, 1928, p 1,352) comments on the difficulty in recognizing phthisis in adults in its early stages, in doubtful cases not one but several examinations, at weekly intervals, are required, so that the progress of any symptoms and signs may be watched. The previous history is important, also heredity and social conditions. A history of pleurisy with effusion is suggestive, and influenza may mask incipient tuberculosis. Changes in the chest formation and its movements should be looked for, but deep breathing should not be required until auscultation is in progress, since it may remove the finer accompaniments. The temperature and its fluctuations are important, even though no organic disease can be found in many cases of such febrile temperature of long standing. Patients may improve temporarily with treatment and change of air, and many of them keep well even at exacting occupations, but they require careful investigation and supervision. Increase in the pulse rate is a bad sign. Loss or gain in weight is important gain while at work especially of the manual kind, contraindicates the presence of any progressive tuberculosis. Percussion and auscultation may be misleading, since a case with marked physical signs may be healed or stationary, and there are many variations even in the normal chest. Shortening of the percussion note is a frequent finding in phthisis, there may, however, be no alteration in the note in an early case and conversely, dullness may persist harmlessly for many years if due to scar formation. Comparative auscultation is less reliable at the apices, because the breath sounds on the right side often approximate more nearly to bronchial breathing even in the healthy chest.

402 Undulant Fever in Denmark

MI KRISTENSEN (*Ugeskrift for Læger*, September 6th, 1928, p 869) supplements a paper published last year in that journal (No 49) on undulant fever in Denmark with observations brought up to date. Between April 3rd, 1927, and March 31st, 1928, 222 new cases were diagnosed throughout Denmark on the strength of a typical Widal reaction in a 1 in 100 or a higher dilution. There was no marked seasonal incidence, and it is probable that though no such cases were recognized before April 1st, 1927, they were as numerous before as after that date. The incidence of the disease was two and a half times greater in rural than in urban districts, and its distribution throughout the country was fairly even, with little to suggest concentrated endemic outbreaks. Only in one instance did two cases occur in the same house. Both the chronological and topographical distribution of the cases suggested that every strain of the bacillus in question is pathogenic to man, but only a minority of human beings coming in contact with it prove susceptible to it. The age of most of the patients was between 15 and 40, and the ratio of females to males was as 56 to 166. In this connexion it should be noted that many more men than women in Denmark come into direct contact with cattle. In no case was the disease diagnosed in children under the age of 8, although as many as 102 children under this age were clinically suspect, and their blood was tested (Widal), with a negative result. The mortality as calculated from the author's present and a previous series of cases, was between 2 and 3 per cent. Vesicular stomatitis, palpitation of the heart, a comparatively slow pulse, and haemorrhages such as epistaxis were among the most prominent symptoms. In as many as 49 cases the general condition was remarkably good, in spite of high and protracted fever. The average duration of the fever was seventy five days, and the average duration of incapacity to work was about four months. Blood cultures were made in 29 cases and Bang's bacillus found in 18 or 62 per cent. In no case were any other germs grown to which a pathogenic role could be imputed. Though infection from man to man cannot be categorically denied, it is probable that this risk is very small, provided ordinary cleanliness is observed. Treatment consists of rest in bed until the temperature has been normal for several days, patients in whom the fever has lasted for two months or more should not begin to get up till the temperature has been normal for at least a fortnight. Though the treatment is symptomatic rather than specific the correct diagnosis is of importance, since it saves the patient from the ill attending such alternative diagnoses as tuberculosis and typhoid fever.

403 Continuous Precordial Murmur in Hepatic Cirrhosis

GAI LAUARDIN, GRAVIER, and PUIG (*Lyon Méd*, September 16th 1928 p 334) remark that this sign, although very rare, has been observed by several authors who have regarded it as pathognomonic of hepatic cirrhosis. In a minority of cases some venous anomaly has been found. The authors report the case of a chronic alcoholic man, aged 47, who was admitted for atrophic cirrhosis. He had had severe haematemesis before admission, was very anaemic, and had syphilitic aortitis with the characteristic double aortic bruit. During the last fifteen days of life a continuous roaring precordial bruit was heard at the junction of the inferior and middle third of the sternum, it was loudest at diastole and during inspiration, and was sometimes accompanied by slight frissons. It resembled exactly the jugular "bruit de diable" heard in anaemia. At the necropsy the area in which the bruit was heard during life was found to correspond with the right auricle and the junction of the superior and inferior vena cavae. The diaphragmatic arch was abnormally high and the pleurae and pericardium were very adherent, especially on the right side. The heart was moderately hypertrophied, there was extensive syphilitic aortitis, but no other vascular abnormality. The authors add that in every case recorded, with one exception, cirrhosis was present, in the exceptional case the patient had malaria, recent syphilis, and hepatitis with ascites and anasarca, which disappeared under antisyphilitic treatment.

404 Relations between Herpes Zoster and Varicella.

V MISASI (*La Pediatria*, September 1st, 1928, p 933) records an attack of typical varicella in an infant, aged 10 months, being followed ten days later by a typical thoracic herpes zoster in another child in the same ward. Subsequently the majority of the children in the ward developed varicella and a small number herpes. None of the children with varicella showed any signs of herpes or vice versa. Although the problem of the relation of herpes zoster to varicella can only be settled when the specific agent of the two diseases has been identified, the large number of cases of herpes followed, preceded, or accompanied by varicella is in favour of there being a causal relation between the two forms, or at least supports the view that there is a form of herpes of the same nature as varicella (herpes varicelliformis) which is distinct from the other forms of herpes.

Surgery.

405 Wounds Caused by Copying Pencils

G BETTAZZI (*Il Policlinico*, Sez Chir, October 15th, 1928 p 501) reports two cases of wounds caused by copying pencils, and remarks that such injuries have a peculiar course because the coloring matter contained in the pencils has a necrotic action on the tissues and also gives rise sometimes to general toxæmia. A boy, aged 14, came into hospital with such an injury. He had a painful fistulous perforation on the left cheek which was discharging a saffron liquid of a very deep violet tint. The lesion was surrounded by a small violet area and by a large hard zone of oedema which was elastic and pallid. A long incision was made through the swelling and shreds of necrotic tissue were scraped away, all deeply tinged by the coloring substance. After a few days a large eschar separated, comprising skin and underlying soft parts. The oedema disappeared and the wound healed by granulation in 8 months, leaving a flat electric slightly red tint. There was no constitutional disturbance. Bettazzi's second patient was a woman who struck her right hand violently against a recently sharpened copying pencil, the point of which remained embedded in the palm of the hand. After two days she came to hospital with much pain, swelling, and inflammation. The point of entrance of the pencil was of a deep violet appearance with a coloured periphery. The whole arm as far as the axilla was numb, the patient felt ill and her temperature was 102°. A crucial incision was made and a quantity of dead tissue was removed together with the little fragment of pencil, later another incision was made at the back of the hand. The patient was discharged after nearly a month in hospital. Bettazzi remarks that experimental investigations have shown that the coloring substances in aniline dyes have not only a clearly necrotic action but a general toxic power. According to

Glass and Kruger, methyl violet is more toxic to tissues than methyl blue. In animals there is a general reaction, with lesions of the kidney and liver, and with pulmonary haemorrhages, as well as the local action on the tissues. The author concludes that with lesions of this kind it is not enough to extract the fragment, but that every piece of tissue which is in the least altered in colour should at once be freely excised.

403 Poisoning following the Use of Hexamine and Salicylic Acid

H. EDLMANN and H. NÖLLE (*Zentralbl. f. Chir.*, October 13th, 1923, p. 2576) comment further on Edelmann's report of a fatal case of poisoning after the use of hexamine and salicylic acid in a case of anuria following a surgical operation on a boy aged 7 (see *Epitome*, July 21st, para 55). Edelmann maintains his opinion that death was due to poisoning, and refuses any other explanation. Nölle agrees with Vogt that all such cases should be recorded in order to ascertain the actual value of a little known drug which is recommended in cases of pyelitis, pyelo-nephritis, cystitis, and prostatitis, and as a prophylactic after operations on the ureteral tract, and also in the treatment of post-operative and post-partum retention of urine, when these are physiological and not mechanical. Hexamine and salicylic acid preparations (such as cycloprolin) appear to induce hyperaemia of the vesical mucosa, they have also been administered intravenously in cases of meningitis or meningococcal irritation. In one instance slight haematuria followed administration of 4 grains of norepinephrine. The individual tolerance of patients to cycloprolin varies greatly. A debilitated patient, aged 61, complained of slight dysuria after cholecystectomy. An intravenous injection of about 4 grains of cycloprolin was followed by complete retention of urine, and daily catheterization was required for three weeks. Eventually an infrapubic cystostomy was performed, and a considerable area of the vesical mucosa was found to be necrotic. Nölle adds that the first intravenous injection of norepinephrine or of cycloprolin should not exceed 2 grams, and advises smaller doses than this, increasing them later if they are tolerated.

407 Pyloric Achalasia and Peptic Ulcer

D. MARTIN and V. G. BURDEN (*Annals of Surgery*, September, 1923, p. 565) quote Ernst's definition of achalasia as the persistent failure of a sphincter to relax, and suggest that pyloric achalasia gives rise to chronic dyspepsia and ulcer symptoms in the absence of ulcer, it is also a contributing factor in the development of peptic ulcer, and an underlying reason for its chronicity. Pyloric achalasia is the result of disturbed correlation between sympathetic and parasympathetic control, and may be caused by preponderance of sympathetic influence or paralysis of parasympathetic or vagal fibres. The failure of the pyloric sphincter to relax is chiefly operative against duodenal regurgitation, which reduces gastric acidity, and so there is prolonged exposure of the stomach mucosa to a highly acid content, which later causes chemical and mechanical trauma in the duodenum. Nicotine may cause pyloric achalasia by its paralytic action on the sensitive vagal ganglia of the pylorus. Infantile pyloric hypertrophy may be due to intermittent clonic spasm before birth, caused by preponderance of sympathetic influence or impaired development of vagal inhibition. Gastro-duodenal surgery must ensure a ready passage of gastric content and free regurgitation into the stomach of pancreatic and biliary secretion. Judd's ulcer resection, combined with partial pyloromyotomy, the Finney-Hahner operation, and Billroth No. 1 are the most successful methods of securing this result. Resection of the accessible portion of the pyloric sphincter without opening the mucosa offers the best chance of successful results in cases of pyloric achalasia.

408 Megacolon due to Pelvic Sarcoma.

MACAIGNE and FLEURY (*Bull. et Mém. Soc. Méd. des Hôp. de Paris* July 5th, 1923, p. 1113) report the case of a man, aged 67, with a uniform abdominal enlargement of several months' duration. There was general tympanites and dilatation of the superficial veins, but no ascites and no enlargement of the liver. No tumour could be felt either externally or by rectal examination. During his five months' residence in hospital he developed a small epithelioma of the tongue, but owing to his state of ill health no radical operation could be undertaken, there was no evidence of tuberculosis or syphilis. His bowels were slightly open every day, he could not retain any enema, but the passage of a rectal sound gave him much relief. He died from progressive cachexia, and at the necropsy a large sarcoma was found in the pelvis pressing on the colon. There were no metastatic deposits. The growth was situated at the recto-sigmoid junction beyond the reach of the finger. Since there was never any absolute obstruction, and he had difficulty in retaining simple enema, it was not considered advisable to give him a barium enema.

Therapeutics.

703 Antitoxin Treatment of Erysipelas.

D. SYMMERS (*Journ. Amer. Med. Assoc.*, August 25th, 1923, p. 535) maintains that the results of the antitoxin treatment of erysipelas are commensurate with those obtained in the treatment of diphtheria. It does not, however, confer immunity against recurrent attacks, diminish the incidence of complications, or prevent the occurrence of sequels. Facial erysipelas yields more readily to antitoxin treatment than erysipelas of the trunk or extremities. Of 563 facial cases treated at the Bellevue Hospital, New York, 92.1 per cent were cured in from two to seven days, and 1.9 per cent in from eight to fourteen days, while in 0.8 per cent the disease was uncontrollable, even when full doses of antitoxin were administered over a period of many days. Of the 563 patients 28 (4.9 per cent) died. In a series of 489 patients with facial erysipelas treated without antitoxin during the previous years 26.7 per cent were cured in from three to seven days, and 49.2 per cent in from eight to fourteen days, while 15.1 per cent required from fifteen to fifty three days, and death occurred in 8.7 per cent. In a series of 142 patients with erysipelas of the trunk treated by antitoxin, 78.1 per cent were cured in from three to seven days, 9.8 per cent in from eight to fourteen days, and in 3.5 per cent the treatment had no effect. Death occurred in 8.4 per cent. In a corresponding series of 92 cases treated without antitoxin, 18.4 per cent recovered in from four to seven days, 42.3 per cent in from eight to fourteen days, 16.3 per cent in from fifteen to forty six days, and 22.8 per cent died. Symmers adds that the intramuscular route offers the best method of introducing the antitoxin, intravenous injection is dangerous, and should only be employed in desperate cases.

410 Cardiac Contraindications to Ephedrine Administration.

W. A. BLOEDORN and P. F. DICKENS (*Arch. Int. Med.*, September, 1923, p. 322) call attention to the dangers attending the administration of ephedrine in heart failure. They report a case in which serious cardiac embarrassment with pulsus alternans, tachycardia, and cardiac decomposition, followed its use for "asthma." The patient, a man, had complained for several weeks of shortness of breath on exertion, an acute attack of dyspnoea occurred once at night, and, lasting for several hours, was diagnosed as "asthma." This was "cardiac" rather than "bronchial asthma," since there was no eosinophilia. There was only a single paroxysm of dyspnoea, occurring late at night after a fatiguing day in a patient who had shown previous evidence of a failing myocardium for several weeks, and in whom there was never any return of symptoms suggestive of bronchial asthma, marked improvement under rest and digitalis therapy established a diagnosis of cardiac failure. For this so-called "asthma" he had been given 3/8 grain of ephedrine, taking forty doses during the next twenty days—a total of 15 grains. Following its administration he developed signs of acute cardiac decompensation, with marked dyspnoea, sweating, tremors, weakness, palpitation with a cardiac rate of 160 per minute, pulsus alternans, and a large right pleural effusion. He complained that while taking the drug his condition became worse, and that after each dose the symptoms increased. With the discontinuance of the ephedrine and the administration of digitalis, with complete rest in bed, he steadily improved and the effusion disappeared. The authors contend that this case illustrates the danger of using ephedrine for patients with damaged hearts. They advise its use only after a careful cardio-vascular examination and with very great caution in the presence of any cardiac damage, the drug should be discontinued on the slightest development of any toxic symptoms. The case also illustrates the mistaken diagnosis of bronchial for cardiac asthma, and the need for cardiac examination even when true bronchial asthma is present. The authors add that on account of its danger in certain cases its open sale should be discouraged, since it is becoming more frequently used by laymen without consulting a physician.

411 Radiotherapy in Hodgkin's Disease.

HARET and LIECHTIZ (*Journ. de Radiol. et d'Electrol.*, October, 1923, p. 501) do not believe that radiotherapy hastens the course of Hodgkin's disease, and maintain that irradiation by x-rays produces marked benefits, transitory though they may be. By this treatment all the symptoms are ameliorated, the ganglionic masses diminish, the fever and sweats disappear, the appetite improves, weight increases, the erythrocytes and haemoglobin increase, the leucocytosis decreases, while the leucina, pruritus and spontaneous pains cease. No other treatment, including sodium cacodylate, thorium x, and vacolins, has proved so efficacious,

and radium has not given as good results as x rays. Operative treatment, especially when the disease is advanced, is attended with very grave risks. Irradiation should be started as early as possible, since in the early stages of the disease remissions are obtained more rapidly and maintained for a longer period, in the later stages patients apparently become radio resistant, and remissions are less complete and less prolonged. The authors report four cases treated during the past year. Three of these were advanced with pulmonary granulomatosis, and treatment had little effect. The fourth patient improved so much as to feel well enough to return to work. The effects produced by x rays are attributed to the great radio sensibility of lymphoid tissue. Dosage is governed by two conditions: the proportioning of the tension and filtration to the depth of the lesions, and the absorbing of considerable quantities of the rays without damage to the skin. For superficial adenopathies, some deep irradiation is employed—namely, 25 cw. k. v. with 5 mm. aluminium filtration. The spleen is irradiated over many ports of entry, but each cutaneous segment should not receive more than 600 R weekly, nor should each session be too prolonged. In deep seated lesions rays of greater penetration should be employed—namely, a filtration with 1 mm. copper or zinc plus 2 mm. aluminium and an anticathode skin distance of 30 cm. Each treatment should not exceed 1,000 R. Even when improvement has occurred it is advisable to continue the treatments at intervals over a sufficiently long period.

Laryngology and Otology.

412. Indications for Treatment in Tuberculous Laryngitis

H. CABOCHÉ (*Arch. Internat. de Laryngol.*, September-October, 1928, p. 897) insists that the important factors in the treatment of tuberculous laryngitis are the measures applied to curing the general or pulmonary condition, including the dietetic and hygienic procedures, the use of artificial pneumothorax, and the silence method. All local treatment of the larynx should be preceded by inhalation of some antiseptic. Such surgical measures as laryngectomy and laryngostomy are not indicated in tuberculous laryngitis. Epiglottidectomy is of considerable use in cases where there is necrosis of the free edge of the epiglottis and the larynx is elsewhere free; the author thinks that the operation would be better performed by diathermy. Application of lactic or trichloroacetic acid is restricted to cases of ulceration of the vocal or ventricular bands. Intralaryngeal surgery consists in the removal of vegetations. In almost all cases the best line of treatment is by galvanic cautery. Heliotherapy and actinotherapy have occasional good results, but these are much more numerous where the light is associated with the electric cautery. Radiotherapy does not appear to have any useful results and diathermy is very difficult of application. Caboché thinks that almost all cases of tuberculous larynx are in themselves curable, but they must be taken under control early and completely. If the patients do not receive sanatorium treatment and care their chances are lessened, and if they have to attend hospital out-patient clinics for all their treatment the prospect of recovery is poor.

413. Drainage of the Cisterna Pontis Lateralis

A. LEWY (*Arch. of Otolaryngol.*, June, 1928, p. 614) describes the operation of draining the cisterna pontis lateralis in cases of otogenic meningitis. He describes the cistern as being an arachnoid space communicating with the cisterna magna and extending outwards as far as a line between the internal auditory meatus and the opening of the duct of the cochlea. It includes both these openings and the seventh and eighth nerves, which lie free in it. The radical mastoid operation is performed, and the middle and posterior and middle fossae are uncovered. Bone is then removed in front of the lateral sinus and from behind and above the facial ridge. In cases where the labyrinth is involved the operation is continued through this structure, otherwise it is respected as far as possible. The dura mater is separated from the posterior surface of the petrous bone until the level of the internal auditory meatus is reached and the cushion like projection of the cistern is seen. The dura is here incised and cerebrospinal fluid gushes out, accompanied in many cases by pus. The cistern is then packed with an iodoform strip, this is removed after seventy-two hours and a light packing is substituted without inserting it into the cistern. Intravenous injections of methenamine are also given. The author has employed this operation twice, with one recovery and one death of six other reported cases three patients recovered and three died. He considers that it gives the best drainage in these cases and obviates the necessity for repeated lumbar punctures. It is useful in cases where meningitis is still confined to the posterior fossa.

414. Insulin Treatment of the Diabetic Mastoid

G. SALADORI (*Arch. Ital. di Otol.*, August, 1928, p. 463) reports three cases of acute suppurative disease of the middle ear and mastoid process in diabetic subjects, and describes their reaction to insulin. The first patient was a man, aged 56, with acute otitis media and tenderness over the mastoid process, there was a small perforation and some discharge. The urine contained 1.8 per cent of glucose and the blood 0.23 per cent. He was at once put on a diet containing 40 to 50 grams a day of carbohydrate and given a course of 10 units of insulin daily. In three days the glucose in the urine had almost disappeared and the pain in the ear had ceased. The second patient came with a definite degree of mastoiditis, following neglect for a month. The mastoid region was opened up and drained by Schwartz's method. The urine was found to contain 2.4 per cent of glucose and the blood 0.21 per cent. The patient was allowed carbohydrate, and was given daily doses of 5 units of insulin, and later 10 units. The mastoid region and the middle ear were perfectly healed and dry in less than two months. The third patient was a man who had suffered from diabetes for two years, there developed acute otitis media, symptoms of mastoiditis, and then diabetic coma. He was given 100 units of insulin a day, having 0.4 per cent of glucose in the blood, after fifteen days the blood sugar had returned to normal and the ear condition had completely resolved. Salvadori remarks that in diabetes there tends to be a condition of arterio sclerosis in the smaller vessels, a diminished production of leucocytes and antibodies, and reduced phagocytosis, any inflammation tends to spread very rapidly. Administration of insulin improves the general and the local conditions swiftly.

415. Treatment of Rhinophyma.

A. POROSZ (*Lof. and Cut. Rev.*, August, 1928, p. 519) states that rhinophyma consists essentially of bulbous, lobulated, and poulous swellings, affecting as a rule the lower part of the nose. Some are smooth to the touch and others are rough. The nose sometimes possesses the normal colour, but more often is of red or purplish hue with enlarged veins and enormous dilated sebaceous follicles. Numerous methods of treatment have been advocated. Juliusberg recommends resorcin beta naphthol ointment of such strength as to cause desquamation of the upper layers of the skin. The method, however, is a tedious one, and is quite useless in marked cases. Schaeffer uses mild x ray doses or carbon dioxide snow in the early stages. Unqualified success, however, is attained in such cases by surgical treatment. Skin grafting is required for extensive operation wounds. Porosz regards the electric cautery as indispensable for securing good results. It also has the advantage of making the operation bloodless. The operation is completed in forty-eight days.

Obstetrics and Gynaecology.

416. X-ray Diagnosis of Early Pregnancy

G. ALBANO (*Zentralbl. f. Gynäk.*, August 18th, 1928, p. 2084) states that recent advances in radiological technique have made it feasible to detect elements of the foetal skeleton as early as the end of the third month of pregnancy. Certain observers have obtained x-ray evidence of one and two months' gestations by injecting into the uterus a few cubic centimetres of lipiodol, which give a fairly characteristic shadow below the lower pole of the ovum, the use of this method is not, however, free from the danger of inducing abortion. Albano describes attempts to recognize early pregnancy by screening the patient after injections of opaque substances which are excreted into the liquor amnii. Colloidal iron, as well as colloidal silver and mercurial preparations, contain so little of the metallic element that although some of them pass into the amniotic fluid no distinct shadow is cast. With two iodine preparations, however, and with strontium bromide Albano reports having had more success. Potassium iodide was given in two 1 gram pills, at an interval of half an hour, to the fasting patient in the morning, the best pictures were obtained fifteen minutes after the second pill had been taken, the film being under-developed after an exposure of three seconds. Sodium tetratodophosphatide freshly prepared or after being kept in the dark for twenty-four hours, was given intravenously (30 c.c. of a 10 per cent solution) and the x-ray examination was made similarly thirty minutes later. Strontium bromide was given intravenously and slowly to the amount of 2 grams in 10 per cent solution. Unpleasant symptoms were noted by the patients during the beginning of the injection. The second preparation was found to give the best results. In twelve cases of pregnancy in the first or second month well-defined shadows, regarded as typical of early pregnancy, were made

out in the uterine, these were distinguishable from the findings in two cases of myoma by the irregularity and less density of shadow in the latter condition. Albano adds that there appears to be no available evidence as to the x-ray shadows cast in cases of ovarian cyst or of tubal pregnancy in which the patients have received sodium tetratolol phenolphthalein injections, so that the value of the method in differential diagnosis is not yet fully worked out.

417 An Abnormal Early Uterine Pregnancy

H WOOLLARD and J B DAVISON (*Med Journ of Australia*, August 18th, 1928, p 210) report an abnormal uterine pregnancy of about twenty days' duration. The patient, aged 38, had been married for eighteen years, and the youngest of her three children was 9 years old. Since the birth of this child she had had five miscarriages. For five months before admission to hospital menstruation had been very irregular. For the three weeks immediately previous she had had a daily loss of blood with pain in the right iliac fossa. The last true menstruation occurred thirty-one days before admission. A diagnosis of incomplete abortion was made and the patient was curetted. Among the material removed was a large piece of endometrium, which was found to contain a small ovoid oyst-like body while measured approximately 6 by 4 mm. Serial sections of this showed it to be an ovum of approximately twenty days, bearing a strong resemblance to the photographs of the Bryce Teacher ovum. There was no embryo, the epithelial proliferation was normal, but the villi were enlarged by the hypertrophy of the stroma. The stroma showed fibrous change and possibly hyaline degeneration. It was therefore thought that the villi were undergoing the prolifimentary changes that lead to the formation of a hydatidiform mole. There was no indication of the presence of a foetus. The decidua did not show chronic endometritis. The cause of the hypertrophy of the stroma was not due to changes in the villous capillaries, because those had not yet appeared. It was suggested that the cause of hydatidiform degeneration was to be found in the regenerative control executed by the embryo on the formation and function of the villi.

418 Lactation Psychoses.

MÉNACHE (*Bull Soc d'Obstet et de Gynecol de Paris*, October, 1928, p 807) contributes an account of two cases illustrating the psychoses of lactation. One patient was a woman, aged 32, whose mother had suffered from mental trouble before her death, a sister had had two attacks of acute mania. The patient's previous history contained nothing bearing on the case. She had been confined four times, on each occasion the infant had been breast-fed. An attack of acute mania supervened each time towards the sixth month of lactation, and after weaning and two to three months' stay in an asylum the patient was discharged completely cured. In the second case the patient's family sent for the doctor because for several days she had appeared unusual. Seven months previously she had been normally delivered and was still breast-feeding. At the time of the visit she was seated in a corner, immovable and indifferent, her gaze being fixed and expressionless. Her memory was affected, and she was incapable of executing a command. She was somewhat disoriented in time and space. She seemed to feel nothing and to desire nothing, she had faint visual hallucinations. The child was weaned and a course of general medical treatment was started, in six weeks she was quite cured. Two years later the patient was delivered in a maternity home, and lactation had produced the same results. Similar treatment resulted in rapid recovery. These cases were two of a series of twelve treated by the author, who concludes that the psychoses of lactation show the confusional form in patients without an hereditary taint, and mania in others. They are generally rapidly cured, provided that lactation is immediately stopped. Succeeding lactation psychoses in the same woman are of identical nature. The author insists that it is essential to forbid lactation in any woman who has had mental trouble during her first lactation.

419 Cancer of the Body of the Uterus.

D DEN HOED (*Nederl Tijdschr v Genesck*, September 22nd, 1928, p 4654) illustrates the comparative rarity of cancer of the body of the uterus by the fact that in the Antoni van Leeuwenhoek Hospital there were only fourteen cases, as compared with 300 of cancer of the cervix. The ages of the patients ranged from 30 to 80. The author maintains that in cases of cancer of the body of the uterus, where operation is impossible owing to technical difficulties, the bad general condition, or concurrent disease, treatment by radium and x-rays offers a considerable chance of a cure. In cases of recurrence irradiation is usually the only favourable treatment, and sometimes saves life. In the combination of radium and x-rays special importance is to be attached to intrauterine treatment with radium.

Pathology.

420 The Mechanism of Visceral Pain

In order to test the theory that visceral pain is caused by the normal afferent impulses from the skin entering a cord segment which has become abnormally irritable owing to visceral "bombardment," S WEISS and D DAVIS (*Amer Journ Med Sci*, October, 1928, p 517) have conducted a series of experiments on twenty-five patients with intense and well defined and localized pain due to various pathological conditions of the heart, lungs, oesophagus, stomach, gall bladder, kidneys, and Fallopian tubes. Visceral pain was also induced in normal subjects. The painful area in each case was carefully mapped out, and the corresponding skin areas (varying from 6 to 60 sq cm) were infiltrated with a 2 per cent solution of novocain in order to abolish the cutaneous afferent impulses. The results gave direct support to the theory of referred pain. Afferent cutaneous impulses are closely related to the mechanism of visceral pain, since this ceases completely if the corresponding afferent impulses from the skin are blocked. Novocain infiltration of the corresponding painful skin areas caused prompt relief in patients suffering from severe visceral pain. In the cases of induced pain infiltration of the skin caused relief over the localized area, but the pain became located over another skin area. The pain again became localized over the original area on cessation of the skin anaesthesia. A dull unpleasant sensation (soreness, discomfort, pressure, but never pain) was noticed occasionally after skin infiltration. Whether this is localized in the viscera or is due to certain afferent impulses from outside of the peritoneal or pleural cavity cannot be stated. Following the cessation of the pain, abnormal afferent sympathetic impulses from the irritated viscera may still reach the central nervous system. The present observations, together with those by others on the effect on visceral function of stimulation of certain skin areas, indicate that the relationship between skin sensation and visceral function is reversible. The authors believe that skin infiltration is a practical therapeutic measure in certain conditions associated with localized pain. They discuss the relation between the effect of this infiltration and of paravertebral injection. The identical results of the two procedures suggest that the analgesic effect of paravertebral injection is due rather to the blocking of certain cutaneous impulses than to the anaesthesia of the rami communicantes of the sympathetic chain.

421 Absence of Spirochaetes from the Glands of General Paralysis

H v FISCHER (*Centralbl f Bakt*, 1928 108, p 247) recalls the fact that the *Spirochaeta pallida* can very frequently be demonstrated in the lymph glands of rabbits that have been experimentally infected with syphilis and that have passed into the latent stage of the disease. He therefore determined to ascertain whether spirochaetes could similarly be found in the glands of patients suffering from general paralysis. Eight cases of the progressive form of this disease were studied, of these, six patients had received no specific treatment, one had been treated with the malarial parasite, and one with this organism in conjunction with salvarsan. The general technique was to remove under local anaesthesia an inguinal, an axillary, and a supraclavicular gland, and to inoculate rabbits, using Tomaszewski's scrotal implantation method on one animal, and the intratesticular injection of a glandular suspension on another animal. As it is known that progressive syphilis frequently does not occur in rabbits inoculated directly from human subjects further inoculation of fresh rabbits was made from the primarily inoculated ones. The experiments, in spite of the careful technique employed, all proved negative. In not a single rabbit was evidence of spirochaetal infection discovered. It would appear, therefore, that if spirochaetes are present in the glands of general paralytics, they must presumably be present in only very small numbers—too small, in fact, to be demonstrable by the rabbit inoculation method.

422 The Effect of Glucose upon the Esterification of Cholesterol

In a study of the hepatic functions A ANDRES (*Bratislavsk Lekarsk Listy*, September, 1928, p 508) investigated the amount of free cholesterol and of the cholesterol esters in the blood, and the relation between the two—the "ester quotient." He found a very pronounced decline in the cholesterol esters in diseases of the liver. In some of these cases the esterification of the cholesterol improved distinctly after the administration of glucose. The author suggests, therefore, that the increased esterification is due to an improvement of the function of the liver caused by the administration of glucose, and that the investigation of the cholesterol and its esters in the blood may prove to be a means of measuring the functional efficiency of the liver.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

423. Hyperacidity and Burning Tongue

J SELLEI (*Deut med Woch*, October 19th, 1928, p 1758) distinguishes cases with burning and smarting of the tongue without visible lesions from cases of lingual neuralgia and the glossodynia which frequently occurs in functional nervous disorders (neurasthenia, hysteria) and cancerphobia. This burning sensation is a combination of itching and stimulation of the heat nerve endings, and resembles the sensation occurring in the extremities in Raynaud's disease. As this symptom often accompanies Hunterian glossitis, which is frequently the first sign of pernicious anaemia, Sellei considers that all these patients should have their blood and gastric secretion carefully examined in order to exclude this disease of the blood. In a number of cases of burning tongue which he investigated he found that the sense of taste was unaffected and that the saliva was chemically normal, there was also no evidence that the disturbance was due to sharp teeth or chemical alterations in the material used for dental fillings. It was, however, found that, in addition to the few cases in which achylia was demonstrated and the blood picture gave evidence of pernicious anaemia, a number of patients had other disturbances of gastric and intestinal secretion, and that in particular a moderate degree of hyperacidity of the gastric juice was common. In these cases washing the mouth out frequently with a weak solution of sodium bicarbonate, and the administration of sodium bicarbonate or a soda magnesium mixture, with or without atropine, were usually effective, though it was sometimes necessary to continue treatment for two or three months.

424. Grave Anaemia in Chronic Nephritis.

L RIVET and T LAENEC (*Rev Med Française* October, 1928, p 553) call attention to the obscure pathology in that class of case of chronic nephritis characterized by excess of nitrogen in the blood. The anaemia is not always caused by dilution, for in some cases the blood concentration is normal. Urea is itself probably not responsible for the condition, which is attributed to the incomplete metabolism of some nitrogenous substances possessing high toxicity. The anaemia can either appear spontaneously or be provoked by unsuitable treatment, such as too strict a regime, and repeated bleedings. Gilbert and Tzanac advised the reinjection of the patient's own washed blood to prevent the anaemia arising in this class of case. Treatment consists in trying to raise the number of red cells without increasing the blood urea—a difficult dietetic problem. Repeated blood transfusions have given good results. The authors describe three cases of anaemia in nephritis showing red cell counts of 2,700,000, 1,580,000 and 1,600,000 per c mm respectively. The first two patients died with anaemia, but in the third case the count rose to 2,800,000 after three transfusions, and the patient felt so much stronger that she refused further treatment, left hospital, and tried to resume her work after a rest in the country. She had, however, a serious relapse after two months, and died at home after a further few weeks. The authors add that these observations, made before the methods of Whipple were commonly known, show that in some cases it is possible to produce by careful diet and appropriate treatment a marked and fairly lasting improvement.

425. Suboccipital Puncture.

E DIAZ Y GOMEZ (*La Med Ibera*, September 22nd, 1928, p 249) records thirteen cases, in patients aged from 7 to 49 years, on whom he had performed suboccipital puncture. The quantity of fluid removed was 20 c cm in three cases, 15 c cm in one case, 10 c cm in eight cases, and 5 c cm in one case. In each case the operation proved easier than lumbar puncture and was not followed by any appreciable discomfort apart from slight headache. The technique is relatively simple. The patient sits up or is placed in the left lateral decubitus with the neck strongly flexed and the head supported by an assistant. A lumbar puncture needle is inserted at the level of the third or fourth cervical vertebra and passed obliquely forwards and upwards until the needle strikes the hard surface of the occipital bone. It is then slightly withdrawn and the movement repeated until the sensation is obtained of a membrane being pierced, an indication that the cisterna has been reached. On each advance of the needle it is advisable to aspirate, since sometimes the fluid does not escape spontaneously.

426

Hair-plucking in Typhoid Fever

J D ROLLESTON (*Clin Journ*, May 30th, 1928, p 260) records a case of trichotillomania, which was first described by Haliopian in 1889, but has not hitherto been recorded in connexion with typhoid fever. The patient was a mentally backward and under-sized boy, aged 10, who at the end of the second week of a moderate attack of typhoid fever developed the habit of pulling out the hairs from his scalp. The habit continued for about a month, during a fortnight of which the temperature was normal, and could only be prevented by putting both arms in splints. There was no local source of irritation in the scalp and no ringworm fungus could be discovered. When the boy was shown at the Royal Society of Medicine about two months had elapsed since he had pulled out any hair from his scalp but he had recently been seen to pull out some of his eyelashes. The scalp in the left fronto-parietal region showed an area of alopecia resembling that caused by a ray treatment of ringworm, and the eyelashes of the left upper lid were less numerous than those of the other lids, and some were broken. Haliopian's cases occurred in adults, but several have since been described in children, not so much in Anglo-Saxon countries as in French, German, and Italian races. In some cases trichotillomania is associated with other tics, such as nail biting or plucking at the penis, or with sexual perversion.

427

Rhino vaccination against Diphtheria

G SALVIOLI (*La Pediatria*, July 1st, 1928, p 687) reports his experience in protective vaccination against diphtheria by the nasal route. He injects a few drops of anatoxin into the nostrils alternately, starting with one drop at night and another drop next morning. When the children were subsequently examined by the Schick test it was found that 90.4 per cent were immune. Preliminary experiments showed that the rhino-pharyngeal mucosa was permeable to diphtheria antitoxin. No general or local reaction was noted after instillation.

Surgery.

429

A Conservative Operation for Bunions

E D MCBRIDE (*Journ of Bone and Joint Surg*, October, 1928, p 735) describes an operation for the relief of hallux valgus by which the deformity is corrected without resection of the joint or fracture of the metatarsal. The normal architecture of the toes is also approached and the mechanical force which caused the deformity is corrected. Additional advantages are that the scar is protected from irritation and the time of disability is reduced. An incision two inches in length, is made along the external border of the extensor hallucis longus with its centre over the joint. A downward dissection close to the metatarsal head is then made, the conjoined tendon of the adductor hallucis group is exposed and severed from its insertion. The internal sesamoid, which is embedded in the outer head of the flexor hallucis brevis, is carefully dissected out if necessary, small bone holding forceps being of great use to hold the sesamoid, or a heavy tonsil tenaculum may be helpful. The conjoined tendon of the adductor muscles and the external head of the flexor hallucis brevis are transplanted into the dorsum of the head of the first metatarsal bone. The incision is then retracted medially and a subcutaneous dissection made to expose the bursa and bone prominence on the inner side of the metatarsal head, the vein being avoided. The bursa is dissected out, the bone prominence chiselled away, the toe corrected, and the capsule repaired. The toe is manipulated into a little over correction and a light plaster slipper is applied, which, with the stitches, is removed in seven to ten days, the toe is held in place by adhesive plaster for from four to six weeks. Weight bearing is allowed at the end of two weeks.

429

Cancer of Lower Lip

F R FAIRCHILD (*Arch of Surg*, October, 1928, p 630) suggests a composite technique for plastic repair for cancer of the lower lip. Made up of various steps in other operations, the advantages claimed are that (1) contractures lessening the size of the mouth are avoided, (2) the most radical extirpation of tumour and glands can be performed, (3) the operation can be completed in one stage, (4) the tendency for the lower lip to tighten against the teeth is avoided, and (5) the sulcus in front of the lower incisors is of normal depth.

The steps of the operation are as follows. A vertical incision through the entire thickness of the lip is made on each side of the growth, and the lower extremities of these are connected by a transverse incision at the level of the point of the chin. From the lower outer angles of the space so formed bilateral incisions are carried through the skin and fat downwards and slightly outwards for about three inches. When the flap so formed is dissected free it becomes possible to draw it up, without tension, sufficiently to fill in the deficiency caused by the excision of the lower lip, and a complete lymphatic dissection can be made. The mucous lining for the intraoral portion of this flap is formed by two horizontal incisions through the buccal mucosa, to form on dissection two flaps of mucous membrane which can be drawn to the median line and sutured without tension, their lower borders being sutured to the out edge of the mucous membrane at the margin of the gum. The skin and fat flap having been secured in place by dermal sutures placed obliquely to distribute any tension, the upper border of the united mucous membrane flaps is reflected over its upper margin and sutured to the skin with interrupted chromic catgut to form the vermilion line of the lip. Fitchell claims that this procedure more closely fulfils the requirements of a one stage operation for removal of the growth and gland bearing fat and for the restoration of the lip, than does any other method.

430 Amniotic Fluid as a Preventive of Adhesions.

FOLLOWING previous experimental work on animals, H. L. JOHNSON (*New England Journ. Med.*, October 4th, 1928, p. 661) refers to his previous investigation into the use of amniotic fluid as a preventive of adhesions (see *Lancet*, January 14th, para. 41) and reports further progress. A concentrate of amniotic fluid has been prepared for clinical use, this is essentially a fractionated alcoholic precipitate containing the active principle of the whole fluid, and is obtained from the fluid of cows three to five months pregnant. As the residual proteins are discarded the use of the concentrate eliminates the fear of infection and foreign protein reaction. When employing it, the fluid is first raised to a temperature slightly above that of the body by means of a water bath. The desired quantity is then poured into the field of operation just before closing the peritoneum, the viscera being retracted to allow the fluid to sink deeply into the cavity. Contact of the fluid with the edges of the wound is said to have no adverse effect on healing. Human amniotic fluid is as effective as that of cows. Tables are given showing the benefits resulting from the use of the fluid in 65 Caesarean sections and 30 laparotomies. The mode of action of amniotic fluid on serous surfaces is not entirely apparent, but it seemingly hastens coagulation and also acts as a lubricant. It is not an irritating or dehydrating agent. The fluid may be applied to all serous surfaces, but it should be reserved for use in clean cases. Its effectiveness is conservatively estimated to be 70 per cent. Its effect on post-operative convalescence is an apparent shortening of the usual period of distress.

431 Treatment of Plantar Perforating Disease.

THOUGH many authorities, including Leriche, are doubtful as to the efficacy of periarterial sympathectomy in plantar perforating disease, A. CONTARGYRIS (*Lyon Chir.*, September-October, 1928, p. 543) is inclined to advocate it. Several authorities of a similar opinion are cited, and a case is reported of trophic ulcerations on each foot, one foot healed after sympathectomy, the other, which was not operated on, did not do so. In addition five cases are reported in which definite cures were obtained by this method. In four of these there was a traumatic lesion of the sciatic nerve with a negative Wassermann reaction, the cause of the fifth was not determined, and a Wassermann test was not performed. The author found that the condition occurred in three cases, and believes that cure often takes place only after such recurrence, though he cannot explain this phenomenon. In sympathectomy for this condition the site usually recommended for operation is the femoral artery in Scarpa's triangle. Contargyris in four of his cases operated on the retroiliac portion of the posterior tibial artery (to an extent of 6 to 8 cm.), and in the fifth on the popliteal artery, as there was denudation of the sciatic nerve at this point owing to injury by a bullet. He maintains that the results will be the same whatever artery is chosen, and that, in case of post-operative accidents, it is wise to operate on a vessel of less importance for the vitality of the limb. Sympathectomy produces effect in this disease in two ways: by creating a nutritive activity of the tissues by an increased circulation of the blood, which causes a post-operative vaso-dilatation, and by increasing the number of leucocytes, thus producing a local phagocytosis and sterilization of the wound. Asepsis and rest also play a part, and are valuable adjuncts to operation.

100 B

Therapeutics.

432 Colloid Silver in Septic Conditions.

E. MOOS (*Med. Klinik*, September 28th, 1928, p. 1507) reports good results following the rectal injection of strong colloid silver solution in the treatment of septic conditions. He does not follow any routine, each patient received treatment appropriate to the specific condition, with modification if anaphylaxis or other complications occurred. The author finds that in staphylococcal infections the daily rectal injection of 150 c.c. of a 5 per cent collargol solution is followed by more favourable results than when ordinary medicinal treatment has been employed. A woman, aged 36, with post-agonal staphylococcal sepsis had rigors, articular pains with arthritis of the right knee, endocarditis, and definite enlargement of the spleen. Salicylates and intravenous injection of colloid silver were given without benefit. When daily rectal injections of 5 per cent colloid silver solution were substituted the arthritis disappeared, the temperature fell to normal, and a thrombo-phlebitis of the right basilic vein cleared up. A man, aged 46, was admitted with severe sepsis of unknown origin. He was jaundiced and had severe endocarditis and cardiac dilatation, with arthritis and pleurisy, there was enlargement of the liver and spleen, nephritis, and staphylococcalæmia. All these conditions disappeared after daily rectal injections of 30 c.c. of 5 per cent colloid silver solution. A woman, aged 20, had bilateral pleurisy following puerperal sepsis. Staphylococci and streptococci were present in the blood though the pleuritic exudate was sterile. Hyaline casts and blood were found in the urine. The patient made a good recovery after daily rectal injections of 25 c.c. of the silver solution. Moos has cured ten other patients with staphylococcal sepsis by this treatment, and only one complained of severe burning pain in the rectum after the injections. The sole disadvantage of the treatment is said to be that patients who are seriously ill may not retain the injections. Since 1911, of 64 septic patients, 28 have died, 4 were discharged only slightly better or unimproved, while 50 per cent of the patients recovered. Among the 32 recoveries, 4 patients had received collargol intravenously and 12 had rectal injections of the silver solution. The remaining patients were treated with various other drugs, none of which appeared to yield such good results.

433 Chemotherapy of Pulmonary Tuberculosis.

G. COLTINA (*Riv. di patol. e clin. della tubercolosi*, August 31st, 1928, p. 681) remarks that the chemotherapy of pulmonary tuberculosis is still in an experimental stage, although numerous cures and encouraging results have been reported from the use of various preparations. None of these, however, has an invariably curative effect in pulmonary tuberculosis, even in cases of which the prognosis is generally favourable. The chemotherapeutic preparations which have no toxic action, and are not contraindicated in any circumstances, are the ointment derivatives, lipid substances, and morrhuins. Next in order of efficacy are the copper preparations such as cuproiodine and cuproglucocoll, and the gold preparations triphal and neoarsol. Two other gold compounds, krysolgan and sanocrysin, are liable to cause severe reactions and are contraindicated in renal affections. Generally speaking, chemotherapeutic preparations are indicated in mild exudative forms of pulmonary tuberculosis in young patients who have no other visceral lesions or organic taint.

434 Dextrose Solution as a Styptic.

L. SCHÖNBAUER (*Zentralbl. f. Chir.*, September 22nd 1928, p. 2378) recommends the employment of a 50 per cent. sterile solution of dextrose in distilled water as a styptic, he obtained good results in animal experiments. In liver resection the parenchymatous hæmorrhage was arrested two minutes after applying a swab saturated in the warm solution of dextrose, but larger bleeding vessels required ligature. Healing was uneventful. Subsequently Schönbauer used a similar sterile solution in human patients during operations on the brain and spinal cord. Parenchymatous cerebral bleeding was arrested in two or three minutes after application of a 50 per cent sterile dextrose solution when the use of swabs saturated in a hot solution of sodium chloride had failed. Schönbauer suggests that the styptic effect is due to the direct action of the dextrose solution on exposed mucous fibres which contain glycogen. A weaker solution of sugar (5 to 10 per cent) has also a styptic action, but the former solution acts more rapidly and certainly. The author has also used this solution to arrest hæmorrhage in diphtheric resection of the choledochus and of the lateral ventricle in an operation for internal hydrocephalus.

435 Therapeutic Action of Magnesium Sulphate.

J. ALSTON (*Ontario Med. Journ.*, October, 1928, p. 442) discusses the treatment of inflammation, suppuration, and cancer by magnesium sulphate. From an experience extending over nineteen years he contends that, when directly applied, the salt has the power of restoring to their normal condition tissues disorganized by bacterial toxins and other agents, when administered orally regeneration of epithellium and bone takes place. From his notion on tissue cells Alston suggests that this salt may be of use in the treatment of cancer. The method of employing it consists in the continuous application to the lesion of warm compresses, changed every three or four hours, soaked in a 10 or 40 per cent solution which has been rendered sterile by boiling, the weaker solution being used where there is a limited blood supply, or the affected part of the body may be placed in a bath of the solution. The treatment seems to be equally effective when applied to the unbroken skin, and its value in tonsillitis is seen after the application of compresses to the neck and holding the solution in the mouth. Cures in cases of septic wounds, holls, carbuncles, dactylos, oryepolias, dermatitis, arthritis with effusion, and phlebitis are reported, and notes of six cases of cancer are given in which improvement occurred. Alston refers to the work of Reding and Dustin, who claim good results from intramuscular injections of the drug, notably in the regression of bony and cutaneous metastases in mammary cancer; he contends that its beneficial action is upon the tissue cells rather than upon the bacterial toxin, since it restores something of which they have been deprived, to the detriment of their normal metabolism.

436. Bearedka's Antivirus.

It has been claimed that Bearedka's antivirus, which is a filtrate of old bouillon cultures, assists the tissues in their defense against infective agents. According to H. CARSKY (*Bratislavské Lekárske Listy*, October 1928, p. 555) its administration is advisable in infective processes where it can be brought into contact with the living cells, but not in processes with extensive necrosis and gangrene. The best results are said to have been obtained in suppurative affections of the skin, such as folliculitis, pyodermitis, paronychia, suppurative axillary hydroadenitis, and also in cases of extensive injury with dirty wounds, as well as in operations on infected regions. The author favours the view that the antivirus has local and specific immunizing properties.

Disease in Childhood.**437. Familial Pylorospasm.**

A. BRATUSCH MARRAIN (*Arch. f. Kinderheilk.*, September 28th, p. 93) who records an illustrative case, states that pylorospasm has a certain tendency to attack several members of one family. Cases have been reported in which one of the parents had suffered from the disease in infancy, and one or more of the children have been similarly affected. It is, however, very unusual for three children in the same family to be attacked, previous examples of the kind having been recorded only by Henbner and Finkelstein respectively. Bratusch Marrain now reports cases of pylorospasm in three children whose parents were healthy though their mother was very nervous. The symptoms of pylorospasm developed in each child within the first few weeks of life; two of the cases ended fatally, but one patient recovered under treatment by injections of atropine and frequent small feeds. The author emphasizes the importance of being on the look out for more cases of pylorospasm in families in which there has already been one instance. Conservative treatment in such cases is the more likely to be successful the sooner it is started.

438. Uveo parotid Fever.

L. P. HAMBURGER and A. J. SCHAEFFER (*Amer. Journ. Dis. Child.*, September, 1928, p. 434) record notes of a case of uveo parotid fever which they regard as a manifestation of Mikulicz's syndrome, in which iridocyclitis is an outstanding symptom. The three essential features of the symptom complex, described by Heerordt as febrile uveo parotiden subchronica, are enlargement of the parotid glands, running a chronic course for several months in contrast with the acuteness of epidemic parotitis, an ocular inflammation involving the uveal tract, and a coincident long continued fever of low degree. In many cases no definite etiological agent can be demonstrated, though syphilis or tuberculosis may be a factor in their causation. The authors' patient, a boy aged 12 was admitted to hospital for "sore, red eyes, fever and enlarged glands." He had had mumps two years

previously. Three months before admission he complained of headache and was in bed for a week with fever, after which he returned to school, but a daily afternoon rise from 100° to 101° F. persisted. Two months later the left eye became "red" and the pupil irregular, this was followed in about a fortnight by involvement of the right eye and a gradually increasing swelling of the parotids, which eventually impeded mastication. The conjunctivae of both eyes were injected and there were some deposits on the posterior corneal membrane. Diagnostic tuberculin and Wassermann tests were negative. The condition remained unchanged for a month, until applications of radium were made to the parotid glands, when they rapidly diminished in size, the improvement obtained by three applications continued subsequently. The authors point out that, while antisyphilitic or tuberculin treatment should be given, when there is reason to suspect these conditions as possible causes, expert radiotherapy affords the best means of cure and prevents the destructive sequelae in the eyes.

439. Pneumonia in Infancy and Childhood.

OLIVE SOMERVILLE (*Arch. Dis. in Child.*, August, 1928, p. 194) comments on the diversity of opinion as to the relative frequency of lobar and lobular pneumonia in infancy and childhood, and remarks that the only sound criteria are those based on the post mortem examination and a study of the histopathology. She concludes that broncho-pneumonia is the typical lesion of infancy and early childhood, and is the variable type in the secondary and accessory forms; lobar pneumonia is thought to be exceptional in the first three years of life. In a study of the pathology of 65 cases of pneumonia only one typical instance of lobar pneumonia was found, and this was in a child of 5 years. Of 35 cases of acute primary pneumonia all showed other typical lobular lesions, or lobular lesions with a lobar distribution and pathology. In the influenza cases consolidation was always lobular in nature. Pure pneumococcal infections occurred in both lobar and primary broncho pneumonia, but other organisms were also found.

Obstetrics and Gynaecology.**440. Caecal Volvulus in Pregnancy.**

ACCORDING TO G. RADAELLI (*Ann. di Ostet. e Ginecol.*, September 30th, 1928, p. 1085) intestinal obstruction occurs in only one out of forty or fifty thousand pregnancies. To the seventeen cases already reported in which the caecum participated in a volvulus the author adds another. A primipara aged 45, in the ninth month of an otherwise normal pregnancy, was seized with sudden and violent abdominal pain which was followed by vomiting; she died twelve hours later, shortly after Caesarean section. The necropsy showed intense congestion of the portions of the alimentary canal supplied by the superior mesenteric artery, and a volvulus of the caecum, ascending colon and small intestine. As a predisposing cause a common ileo-colic mesentery was found to be present. Volvulus of the caecum has been reported to be associated in about one fifth of cases with pregnancy from the fifth to the ninth month. Intestinal obstruction from caecal volvulus in pregnancy has proved fatal in the majority of cases—in three cases as early as the seventh to the twelfth hour after the first appearance of symptoms. It is most common in first and second pregnancies, and towards term, the patients are in general older than those suffering from volvulus of the sigmoid.

441. Hydramnios with Uniovular Twins.

M. MUEL and H. VERMELIN (*Gy. et Obst. t.*, September, 1928, p. 217) report that in a series of 100 uniovular twins 43 were normal, 43 were associated with hydramnios due to deep anastomoses between the two parts of the placenta, and in 14 the hydramnios was attributed to superficial anastomosis, or to causes which might be encountered in simple or twin pregnancy. The investigation of the anastomosis was carried out by the injection of a gelatinous solution containing metallic salts (opaque to x rays) in suspension, with different colouring matters added. X-ray photographs of the injected placentas were then taken. The results confirmed those previously obtained by Schatz, who considered that unequal development of twins was due to an unequal circulation caused by deep anastomosis; the extreme result of this condition being the oedematous foetus in a hydramniotic pouch. In the cases in which hydramnios was due to pathological conditions peculiar to uniovular twins the authors invariably found that the deep placental anastomoses constituted a circulation of transference—a

part of the blood of one foetus (transfusé) passed into the circulation of the other (transfusé). Neither the difference in the size of the two foetuses, nor the difference in the superficial area of the placental territories, indicated which was "transfusé" and which "transfusé". Moreover, the presence of hydramnios was not a characteristic peculiar to either, examination of the vessels was the only way to make this distinction. For example, the foetus A was the active "transfusé" when it sent an artery into the territory of the "transfusé," B, and, whether A was equal to, less, or greater than B, it was always found that B had hydramnios. Alternatively, the foetus A was passive "transfusé" when B sent a vein into the territory of A, but, whether A was equal to, less, or greater than B, it was always found that B had hydramnios.

442. Radiological Diagnoses in Obstetrics.

M. FAVREAU (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, October 10th, 1928, p. 727) commends skiagraphy of the foetus as a valuable diagnostic method auxiliary to clinical examination. The results are considered unreliable before the fifth month of pregnancy, although the author claims to have been successful in taking a skiagram which showed a faint outline of the foetal vertebral column before the fourth month of pregnancy. The result may be uncertain when the actual age of the foetus is less than the estimated age, or when the foetus is dead and macerated. The differential diagnosis of pregnancy and of uterine or ovarian tumour is considerably facilitated, but the recognition of an extra-uterine pregnancy is more difficult. Foetal deformities, especially hydrocephalus and anencephaly, may be diagnosed prior to confinement, and also twin pregnancy, although in that case a very minute examination of the skiagrams is required to avoid error. Foetal death may be recognized by the overlapping of the cranial bones, accompanied by collapse of the cerebral contents. The presentation and changes in position will be recognized easily. The placentas must be examined carefully with the negative screen. The author uses short exposures—namely, two seconds for an antero-posterior skiagram, and three seconds for a transverse exposure. He recommends a Potter-Bucky anti-diffusion screen in order to obtain sharp shadows. The technique must be precise if good results are to be obtained. Favreau adds that x-rays are absolutely harmless when the exposures are so short—they cannot injure either mother or foetus.

Pathology.

443. Sero-haemo flocculation Test for Tuberculosis.

A. PRUNELL (*C. R. Soc. de Biologie*, October 19th, 1928, p. 1110) describes a new serological test for the diagnosis of tuberculosis which is similar to the ordinary complement fixation test, but, instead of using a specific red cell haemolysin, a 1 in 500 solution of acetic acid in physiological saline solution is employed. In the first part of the test a mixture is made of the patient's serum, the tuberculous antigen (a modified Roquet and Néron antigen), and the adjuvant disperser, which is merely a 1 per cent solution of normal human serum, added to prevent the anti-haemolytic effect of certain sera. After fifteen minutes in the water bath at 30°C. varying quantities of the acetic acid solution are added together with the washed red cells. After a further period of incubation, readings are made to determine that quantity of acetic acid solution which will cause haemolysis in five to ten minutes. In the second part of the reaction one tube is put up containing the serum to be examined, the normal serum, and the antigen, another tube contains the same mixture, except that the antigen is replaced by saline. After preliminary incubation, the acetic acid and red cells are added, and the tubes are again incubated. If the serum contains tuberculous antibodies there is no haemolysis in the first tube; the second tube, which contains no antigen, acts as a control and should always show haemolysis. The author has examined the serum from 50 patients whose sputum contained tubercle bacilli, in 35 a strong reaction was obtained, in 9 a weak one, altogether a positive reaction was therefore observed in 88 per cent of cases.

444. Extraction of Toxic Substances from Bacteria.

N. FUJIOKA (*Zell-Immunität*, September 1st, 1928, p. 466) has continued Cleser's work on the extraction of toxins from different bacteria by the use of salt solutions. He first worked with the haemotoxin of the *Librio laticox*, using rabbit blood cells for its titration. In 8 and 16-hour broth cultures of this organism there is no trace of toxin, in 24-hour cultures a small amount can be detected, while in 48-hour

cultures large quantities are present. The author found, however, that considerable quantities of toxin could be extracted if the centrifuged cells from young cultures were treated with sodium or potassium chloride, or sodium or potassium iodide. Treatment with the divalent metallic salts, such as the chlorides of calcium, barium, and magnesium, had no such effect. It appeared from this experiment that the sodium and potassium salts increased the permeability of the cell wall and allowed the toxin to diffuse out. The calcium, barium, and magnesium salts have the opposite effect, they decrease the permeability of the cell wall and prevent the diffusion of toxin. That this is true was shown by a second experiment. The bacilli from a young broth culture were treated with the different salt solutions and with broth, they were then centrifuged down and treated with potassium chloride solution. It was found that the bacilli treated with broth yielded up a large amount of toxin when extracted with the potassium chloride, the bacilli treated with sodium and potassium salts yielded a small quantity, while those treated with barium calcium, or magnesium salts yielded scarcely any or none. Working with the diphtheria bacillus, he found again that toxin could be extracted from very young cultures with the sodium and potassium chlorides, but not with the calcium, barium, or magnesium salts. Similar results were obtained likewise with the Shiga dysentery bacillus. From these experiments Fujioka concludes that bacteria do not secrete toxin at all, the toxin diffuses out in broth cultures only from dead bacilli. However, under the influence of sodium, and especially potassium, salts the permeability of the cell wall is so increased that the toxin can diffuse out from living cells.

445. The Mechanism of Pulmonary Silicosis.

P. HOFFERMAN and A. T. GREFF (*Journ. Indust. Hyg.* October, 1928, p. 272) discuss the two explanations offered up to the present to account for the action of silica dust in the lungs, and show the inadequacy of these to explain silicotic fibrosis and silicotic tuberculosis. The oldest of these explanations is the "direct injury" theory, according to which silica dust, owing to the hardness, sharpness and insolubility of its particles, produces minute wounds in the lung substance, the resulting little nodules of scar tissue constitute the typical silica fibrosis. The second explanation is the chemical theory of Gye, Purdy, and Kettie, according to which silica is a cell poison and brings about its results by its chemical action on the tissues and cells. The present authors suggest an alternative theory to explain the phenomena occurring in pulmonary silicosis. They show that silica is an ordinary constituent of animal and vegetable tissues, and is found in the urine, and they hold that the evidence is strongly against the theory that the silica ion is toxic to animals. Silica in stable combination and crystalline silica appear to be harmless while in those states. Colloidal silica is harmful to certain animal tissues when brought into surface contact with them, when administered intravenously in sufficiently large doses and in an active colloidal condition it may cause immediate death. The harmful effects of colloidal silica appear to be due to its powerful potentialities as a colloid, rather than to any toxicity of the silica ion. The authors suggest that pulmonary silicosis is probably caused by the colloidal action of hydrated silicic acid, formed from minute particles of silica dust disseminated through the lungs. The activity of colloidal silica in the lungs can be prevented by protecting the silica dust with a coating of something, such as clay substance, carbon, or shale dust, which is known to coagulate colloidal silica. Evidence of this has been obtained in the lungs of silica brick makers, noted by Smith and Collins in Yorkshire, and by Hofferman in Derbyshire. The authors believe that possibly other colloids, such as stannic acid sol, may be capable of acting in the tissues in a similar manner to hydrated silica, and they add that perhaps a hereditary phenomena bearing on immunity, susceptibility and resistance to disease may be explained on the basis of colloidal physics.

446. The Testicular Hormone.

G. PERACCHIA (*Arch. di Chir.*, August, 1928, p. 636) admits that beneficial results have followed testicular transplantation and has tried to determine experimentally which part of the organ is responsible for these effects. The test he used to determine what change followed such transplantation was the estimation of basal metabolism as shown by the respiratory metabolism. As the result of experimental work on dogs he concludes that any changes due to the testicle depend on the seminiferous coils, and not on the interstitial tissue as some authors have stated. His investigation convinced him that the interstitial cells, as tested by their effect on basal metabolism, were unimportant as far as the internal secretion of the testicle is concerned, and he believes that the cells of Leydig are only connective tissue elements.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

547 Combined Antityphoid and Antidiphtherial Inoculation

V. NOURY (*Thèse de Paris*, 1928, No 378) states that Ramon and Zoeller (1926) were the first to record cases in which vaccines against two distinct diseases such as tetanus and diphtheria, tetanus and typhoid fever, and diphtheria and typhoid fever, were employed, the individuals being young soldiers. Their successful results induced L. Martin, Leloueu, and Laffaille to use a combination of diphtheria anatoxin and T A B vaccine for protecting young nurses. The author's thesis is based on his observations in L. Martin's service at the Hôpital Pasteur, his conclusions are as follows. The association of antityphoid and antidiphtheria immunization is applicable to all individuals and communities likely to contract typhoid fever and diphtheria, such as doctors, students, nurses and recruits. Four groups may be distinguished: (1) Those with a positive Schick reaction who have not had typhoid fever should be given a mixture of T A B vaccine and diphtheria anatoxin. (2) Those with a positive Schick reaction who have already had typhoid fever should be given anatoxin only. (3) Those with a negative Schick reaction who have not had typhoid fever should be given T A B vaccine only. (4) Those with a negative Schick reaction who have already had typhoid fever need not be vaccinated. The technique of combined vaccination is as follows: A first injection is given of 1 c.c.m., consisting of 0.5 c.c.m. of T A B and 0.5 c.c.m. of anatoxin, this is followed by a second injection of 2 c.c.m. consisting of 1 c.c.m. each of T A B and anatoxin, a fortnight after the first injection, and a third injection of 3 c.c.m., consisting of 1.5 c.c.m. each of T A B and anatoxin, a fortnight after the second injection. Whenever possible a control Schick test should be performed in the following month. The histories of six illustrative cases in nurses is recorded.

548 Congugal Syphilis

A. JORDAN (*Derm. Week*, October 6th, 1928, p. 1578) states that since Lévaditi and Marie drew attention to the possibility of a special nervous syphilitic virus, and the occurrence of nervous syphilis in husband and wife has been found by various observers, the course of congenital syphilis has aroused great interest. As the result of examination of 117 syphilitic families Nonne came to the following conclusions: In only 23 per cent was the effect of syphilis confined to the first member of the family to be infected. The husband or wife who was first infected was more frequently attacked by a syphilitic nervous disease than the one who was next infected. A similar course of the disease in husband and wife was very rarely observed. The disease of the husband or wife who was the second to become infected usually ran a latent course. Well marked symptoms were relatively frequent in the absence of any nervous changes due to syphilis. This observation indicates that syphilis loses its virulence by passage through the nervous system. Jordan now records his observations on 100 married couples, in 94 of which the wife had been infected by the husband and in 6 of which the husband had been infected by the wife. Although the number of cases of nervous syphilis were almost equal between the two sexes, in only 2 cases did nervous syphilis occur simultaneously in husband and wife. There was one example of simultaneous aortitis. Jordan's observations did not furnish the least evidence in favour of the existence of a special nervous virus, but the development of nervous syphilis could always be explained by the more or less complete absence of treatment. The most interesting cases were those of 22 wives who either had a permanently latent syphilis, or who had latent syphilis for a long period, after which late syphilitic manifestations suddenly developed.

549 Addison's Disease in the Negro

L. S. EVANS (*Amer. Journ. Med. Sci.*, October 1928, p. 499), who records three illustrative cases, states that Addison's disease is supposed to be very rare in negroes. In spite of the prevalence of tuberculosis among them. The disease, however, is easily overlooked, owing to the natural pigmentation both of the skin and the buccal mucous membrane. Evans, therefore, is of opinion that the disease is much commoner among negroes than is usually thought. His first case was that of a woman, aged 46, in whom the duration of the illness was

about four years. The chief symptoms were vomiting, dull aching pain in the back and legs, gradually increasing darkness of the skin, and extreme weakness. The blood pressure varied between 70 and 80 systolic and 56 and 62 diastolic. Treatment consisted in rest in bed, a high carbohydrate and low protein diet, and subcutaneous injections of adrenaline, $\frac{1}{10}$ grain, three times a day. Death ensued, and the diagnosis of Addison's disease was confirmed at the necropsy. In the other two cases, which occurred in women aged 43 and 36 respectively, the diagnosis was based on the marked asthenia, generalized pigmentation, dyspepsia and vomiting, and low blood pressure. Both ended fatally, and no necropsy was permitted.

550 Interpretation of the Ventricular Electrocardiogram.

R. STANKOVIC and V. ARNOVLJEVIC (*Arch. des Mal. du Cœur*, September, 1928, p. 598) describe their method for determining the relation of the T wave of the electrocardiogram to the contraction of the ventricles. They selected for this investigation patients suffering from mitral stenosis and having a pronounced reduplication of the second sound at the base. By making simultaneous tracings of the carotid pulse and the heart sounds, they demonstrated that the first part of the reduplicated sound corresponded with the diastolic notch of the carotid curve. Since this incision represents the beginning of ventricular relaxation, the closure of the aortic valves is related to the first of the reduplicated sounds. Simultaneous records were then made of the carotid pulse, the electrocardiogram, and the heart sounds. These demonstrated that the second part of the reduplicated second sound fell always after the diastolic wave, and was followed later by the P wave of the electrocardiogram. This sound, therefore, could only be due to closure of the valves of the pulmonary artery. Further examination of these combined tracings showed that the T wave always bore a constant relation in point of time to the first part of the reduplicated second sound, while the second part was independent of the T wave. It was concluded, therefore, that this part of the electrocardiogram represents the conclusion of left ventricular systole.

551 Temporary Amaurosis complicating Pertussis

A. LITVAK (*Amer. Journ. Dis. Child.*, October, 1928, p. 789) reviews the literature relating to eye disorders in whooping cough, including the case of optic neuritis reported by Hogg (*Epitome*, October 1st, 1927, para. 300), and records a case in a boy, aged 19 months, suffering from whooping cough, who had several convulsions, followed by weakness of the arms and blindness. The fundi were normal. Vision began to return in about six weeks. The condition was probably due to meningeal or intracerebral haemorrhage, or acute encephalitis.

Surgery.

552. Indications for Manipulative Surgery

A. G. TIMBRELL FISHER (*Bristol Med. Chir. Journ.*, Autumn, 1928, p. 165) classifies the types of cases for manipulation in five groups: cases with adhesions, functional or hysterical cases, unreduced dislocations and subluxations, miscellaneous, and combined cases. Adhesions, which are bands of scar tissue due to organization of inflammatory products after injury, give rise to pain, weakness, tenderness, limitation of movement, and recurrent effusion. They may be synovial, capsular, or extracapsular, and are common after diseases of joints, such as synovitis or arthritis. Fisher considers that adhesions are often preventable by the institution of early movement in the treatment of injuries and diseases of joints, and he advocates rest combined with early movement through complete range. The results of manipulation in cases of synovitis of the knee following a sprain of the internal lateral ligament, in cases of rheumatoid arthritis after the subsidence of the acute symptoms, for tennis elbow, or myositis ossificans have been very satisfactory. The most dramatic results occur in cases of functional or hysterical condition, as manipulation is the most effective therapeutic measure owing to the powerful suggestion of the anaesthetic. Treatment by suggestion should precede and follow the anaesthetic. In cases of the "chronic back" the results of manipulation, followed by re-education of the spinal muscles, are often almost miraculous. Manipulation is of great value

In recent and recurrent cases of fracture dislocation of a semilunar cartilage, which must be reduced so that the patient can extend the knee fully and without pain. Gentle exercises (rotary movements being avoided) can be started when the more acute symptoms have subsided and effusion is almost gone, as prolonged immobility leads to marked and sometimes irremediable wasting and stiffness. By manipulation the displaced portion may return to the normal position and repair ensue.

453. Division of the Vagi for Pyloroplasty

O. H. MAYO (*Annals of Surgery*, October, 1922, p. 669), discussing the various known causes of gastric or duodenal ulcer, suggests that the influence of the vagi in the chronicity of gastric ulcer may have been overlooked. The pylorus and duodenum obtain their nerve supply from a large branch of the vagus which passes directly from the region of the cardia to the liver. Mayo considers that chronic appendicitis and gall bladder disease have a definite influence on the formation of duodenal and gastric ulcers, which are generally accompanied by pyloric spasm. He suggests that the pyloric spasm precedes the ulcer. In cases where the stomach trouble was reflex, whether secondary to appendicitis or disease of the gall bladder, or both, in addition to the relief of the particular disease found, he has divided the muscle of the pyloric ring at the upper border in the hope of separating the branches of the vagus, and has then doubly tied and divided between the ligatures 2.5 cm above the pyloric ring on the side of the lesser curvature into the wall of the stomach. As it has recently been established by x-ray observations that ulcers in the angle of the stomach cause the greatest spasm of the pylorus, Mayo has lately divided above the angle of the stomach the tissues of the lesser curvature well into the wall of the stomach instead of, as formerly, at 2.5 cm above the pylorus. It has been found that this procedure, in addition to gastric enterostomy or to other operations, has been of benefit for the relief of reflex conditions.

454. Ganglia.

L. CARP and A. P. STOUT (*Surg., Gynecol. and Obstet.*, October, 1922, p. 460) review the literature and record their observations on 255 personal cases of ganglia, their conclusions being as follows: Ganglia are cysts resulting from molasses degeneration of connective tissue. They generally occur in or near attached to capsules of joints or tendon sheaths, but do not communicate primarily with joints or sheath spaces. The degeneration proceeds with fibrillation of the collagen fibres and accumulation of nuclei both within the cells and in the intercellular spaces. This results finally in the disappearance of cells and fibres in a number of adjacent areas. These embryonic cysts coalesce and lead to the formation of larger cavities. The cause of this degeneration is obscure, but it is probably not due to any lack of vascular supply. Ganglia occur most frequently about the wrist joint, volar surfaces of fingers, dorsum of foot, and popliteal region. They are most frequently found in females of slight build. In the second, third, and fourth decades. Trauma does not play an important part in their production. The chief symptoms and signs are pain, swelling, interference with function, and tenderness. A differential diagnosis must be made from tuberculosis of the joint or tendon sheath, lipoma, myxoma, fibroma, osteoma, sarcoma, bursitis, and aneurysm. So many ganglia disappear spontaneously, and after breaking and pressure, aspiration and pressure, or aspiration and injection of a chemical irritant, that operation should only be resorted to when other measures have failed and there are persistent troublesome symptoms. Careful complete excision under strict asepsis and with a bloodless field will probably not be followed by reappearance.

455. Meningitis due to *B. pyocyaneus*

R. PALAZZO and O. E. OTTOLENGHI (*Rev. Sud Amer. de Endocrin.*, September 15th, 1922, p. 616), who record an illustrative case, state that though *B. pyocyaneus* infection of the meninges is undoubtedly rare, a few cases have been published by French and German writers, such as J. Abadie and G. Laroche, Schlegelhaufers, Liskuchen, Sonueuschele, and Klewe and Koch. The disease begins with a slight rise of temperature and headache, but the meningeal process remains latent until meningeal rigidity occurs, Kernig's sign gradually develops, and is followed by muscular contractions, especially of the abdomen and lower limbs, and difficulty in active and passive movements. As a general rule the reflexes are exaggerated. On lumbar puncture the cerebrospinal fluid is at first opalescent, but later becomes more turbid, and contains 1,000 cells or more per c. mm. together with a considerable increase in the albumin. The Pandy and Nonne-Apert reactions are positive and bacteriological examination reveals *B. pyocyaneus*, which is readily stained

with aniline dyes and decolorized by Gram's method. Periods of improvement and aggravation are characteristic of the disease, which often lasts from three to six months. In children, however, the disease is shorter and less severe. In the author's case, which occurred in a man, aged 28, as the result of a gunshot wound of the dorsal spine, the disease lasted four months. Considerable improvement took place under treatment by an autovaccine.

Therapeutics.

456. Epididymitis Treated by Calcium Chloride Injections.

SINCE epididymitis which is neither gonorrhoeal nor tuberculous is disabling and causes economic loss to patients, E. RUPUL (*Am. Journ. Med. Sci.*, September, 1922, p. 399) considers that a line of treatment which will lessen these results deserves serious attention. He describes a method which consists in giving intravenous injections of aqueous solutions of calcium chloride in addition to the routine treatment. To illustrate the beneficial results from these injections Rupul contrasts two series of cases. In the first group of 50 patients only the usual treatment was employed, in the second, of 28 patients, calcium chloride injections were given in addition to observing the cardinal principles of heat, rest, and support. It was found that, while patients of the first group were confined to bed for an average of 4 to 14 days, the average duration for those of the second group was 1 to 45 days. Relief from pain was the first sign of benefit, and the most striking results were seen in patients who continued working but obtained immediate and complete relief after a single injection. Swelling subsided slowly, as would be expected in an acute inflammation. The calcium chloride was given in doses of 0.5 to 1 gram in dilute solutions (10 c. cm. of 5 or 10 per cent of the salt), and the injections were made slowly at the rate of 2 or 3 c. cm. per minute, the pulse rate and general condition of the patient being carefully watched. No harm from the treatment was observed. Recurrence of the inflammation often followed too few injections, and a course of four or five, once daily, is suggested.

457. Pituitary Treatment of Diabetes Insipidus.

D. ADLERSBERG and O. PORDES (*Wien klin. Woch.*, October 18th, 1922, p. 1467) describe two cases of diabetes insipidus treated by the insufflation of powdered pituitary gland extract. A girl, aged 21, had had her right eye enucleated in 1911 for glioma, since that date she had suffered from severe thirst, polyuria, and more recently from lassitude and head ache. She was under developed and dwarfish, and amenorrhoea was present. A skiagram showed that the sella turcica was clearly defined, enlarged, and funnel shaped. The authors found that, when given by the month, pituitary extract and dried powdered pituitary substance were quite inactive, but when the dried powdered posterior pituitary lobe was insufflated into the nasal passages the result was very satisfactory. Shortly after the start of this treatment the concentration of the urine improved and the average daily quantity was reduced. Thirst and polyuria were relieved, but these symptoms recurred during the night when the evening insufflation was omitted. The second patient was a man, aged 26, who had had encephalitis in 1922, he later developed post-encephalitic changes of character, with hysterical attacks, polydipsia, and polyuria. In this case also insufflation of the pituitary powder had a striking effect, the quantity of urine was reduced to one fourth of that excreted previously. The authors conclude that the insufflation of dried powdered posterior pituitary lobe relieves the symptoms of true diabetes insipidus. It does not lose its effect with time, and it is more convenient than hypodermic injection of pituitrin.

458. Insulin as a Fattening Agent.

M. SIGGAARD ANDERSEN (*Ugeskrift for Læger*, October 25th, 1922, p. 1013) has followed the example of Falta of Vienna, who has given insulin to persons suffering from "primary anorexia"—that is, a constitutional state of emaciation and asthenia for which no specific cause can be found. At the Rigshospital in Copenhagen the author has given injections of insulin to seven patients belonging to the above category, and in every instance he has brought about a rapid and satisfactory gain of weight, which, in his first case, amounted to 18 kilos during a residence in hospital of between four and five months. The injections were often followed by a definite sense of hunger and by a better appetite. The improvement was not limited to the gain of weight, the tone of the muscles and the general appearance of the patients also were improved. It would seem that the weight thus gained does

not quickly disappear, and two of the author's patients, examined a month after the last injection, were found to have lost only half a kilo each. Symptoms of hypoglycaemia, characteristic of an overdose of insulin, were observed in some cases, and were quickly overcome by the administration of some carbohydrate food, such as a banana. The author recommends an initial dose of 2 Scandinavian insulin units (8 international units), given three times a day, about half an hour before meals. This dosage may be carefully increased if necessary. The greatest amount administered in the author's series of seven cases was 32 international units, given three times a day. The last injection of the day should not be given late in the evening, for if there is a serious fall of the blood sugar two hours or more after the last meal, the ensuing manifestations of hypoglycaemia may occur during the night and be undetected by the patient or his attendants. Almost every form of primary anaemia may benefit from this treatment, but it is contraindicated by severe debility. Thus it was found unsuitable in the case of a young woman, suffering from nervous anaemia, whose weight was 4 st 7 lb, and height just under 4 feet. A few tentative injections of small quantities of insulin were followed by an increase of her debility and anaemia. Most writers agree that fever is a contraindication on the other hand, gastroptosis and lack of tone of the stomach are indications for it. During this treatment the patient is allowed to eat as much as is desired of a varied dietary containing plenty of carbohydrates.

Neurology and Psychology.

450 Lower Medulla Radicular Compressions

N. PÉRON (Paris *Med.*, October 6th, 1928, p. 294) discusses the symptomatology and differential diagnosis of compressions of the lumbo-sacral cord and its corresponding roots, and states that, as in all compressions of the cord, when once the diagnosis is confirmed, a double problem presents itself. The condition is due either to vertebral tuberculosis with a secondary meningeal reaction involving the cord and roots, or to a tumour in the nervous elements and meninges. In the first case surgical intervention is absolutely contraindicated, in the second, as early an operation as possible is advisable in order to avoid the paralytic and urinary complications which quickly supervene. Primary tumours of the cauda equina and terminal cone of the cord present a characteristic clinical picture. Their evolution, which is usually slow and progressive, presents three stages—namely, the onset, a period of established disease, and a stage of complications and terminal cachexia. The onset is marked by luteous pain (the earliest symptom), which may be mistaken for rheumatism, lumbago or sciatica. The pain soon becomes bilateral and radiates into the perineal and gluteal regions. Vesical and intestinal troubles though much rarer, may be present. This is the commonest period of diagnostic error. In the second stage symptoms of four types appear: motor troubles, which cause a flaccid paralysis with muscular atrophy; subjective and objective sensory troubles, visceral and sphincteric disorders, and, finally, trophic disturbances. The motor troubles are essentially marked by a paraplegia due to the lesion of a peripheral neuron. The muscles of the leg and foot are first attacked, later those of the posterior thigh and the glutei become involved. The sacral, Aohills peroneo-femoral, plantar cutaneous, and anal reflexes are abolished; the patellar reflex is often normal, while the cremasteric and cutaneous abdominal reflexes are most frequently persistent. Sensory troubles are marked by intense, spontaneous pains and insensibility to such stimuli as touch and heat, anaesthesia of the perineal and gluteal regions occurs. Visceral and sphincteric disorders are also largely constant. Difficulty of micturition with, later, incontinence, constipation, with periods of incontinence and gait, and genital impotence, are usually present. The most marked trophic disturbance is sloughing of the anasthetic zones which has a tendency to extend deeply. Other later trophic troubles are tendinous contractions, with equinus of the feet and clawing of the big toes. Radiography and lumbar puncture are indispensable aids to diagnosis. The spinal fluid, which is yellow and xanthochromic, usually shows an enormous amount of albumin without any cellular reaction, and may coagulate spontaneously. Patients generally become cachectic and succumb to infection. The tumours are often huge and present characters of great malignancy. Their diagnosis is frequently difficult, and they must be distinguished from Pott's disease, secondary vertebral cancer, and from certain inflammatory conditions, such as low spinal syphilis, localized meningitis, medullary affections and peripheral neuritis. Surgery is the only treatment and success depends on early diagnosis and intervention, as well as on the nature of the tumour itself.

450 Sensory Phenomena following Removal of a Tumour of the Sensory Cortex

I. M. ALLEN (*Journ. Neurol. and Psychopathol.*, October, 1928, p. 133) reports a case of meningioma of the post Rolandic sensory cerebral cortex on the left side in which, after the removal of the tumour, three types of abnormal "stereognostic" phenomena occurred: (1) spontaneous sensations of the presence of solid objects in the right hand, gradually decreasing during the six days following operation, disappearing on the seventh day, but reappearing at intervals for five weeks; (2) sensations as of the presence of solid objects in the right hand when they were actually present and felt in the left hand; (3) persistence of sensations of the presence of objects in the right hand after they had been removed from it. Allen discusses these phenomena carefully and suggests possible causes, including the effect that accidental positions of the affected hand might have in the production of spontaneous "stereognostic" sensations. Local impulses might, moreover, arise in the sensory structures immediately above the thalamus as a result of post-operative circulatory changes in this region, and produce spontaneous "formed" sensations, in contrast with "unformed" sensations caused by lesions of, or near to, the cerebral cortex. Another possibility is the effect that post-operative mental fatigue might have in the misinterpretation of the local sensory impulses arising at the supratthalamic level. Allen suggests that the local sensory impulses arose mainly as the result of post-operative circulatory changes immediately above the thalamus, and that mental fatigue and accidental positions of the affected hand were contributory factors in their production.

451 Associated Movements in Organic Cerebral Hemiplegia

DISCUSSING the pathology of the associated movements or synkineses noted in hemiplegia, P. BLANCHET (*Presse Méd.*, September 22nd, 1928, p. 1203) states that these are characteristic of organic cerebral hemiplegia in its spasmodic phase, and never occur, as Babinski has shown, in the functional hemiplegias. These involuntary and generally unconscious movements occur in the paralysed muscles at the same time as other movements—voluntary, conscious, and made with effort—of the muscles of the sound side. Foix and Marjo have defined three varieties of these phenomena: global synkineses, synkineses of imitation, and those of co-ordination. The author believes that the majority of synkineses, of whichever group are due to the fact that each cerebral hemisphere sends out two sets of pyramidal bundles, the direct, the less important, run on the same side as the hemisphere, while the crossed, which the more important, run to the opposite side. It is logical to conceive that, in an organic cerebral hemiplegia (cortical or capsular), if the sound hemisphere initiates the starting, with effort, of movements, these will be bilateral and identical, if not in quantity at least in quality, since the inhibitory power of the diseased hemisphere is suspended, and, under the influence of a strong excitation of the sound hemisphere, the nervous impulse passes down the direct pyramidal tract in quantity sufficient to cause visible muscular contractions on the same side—that is, in the paralysed member. This theory explains the occurrence of the majority, if not of all synkineses, such as the bilateral flexion of the great toes on excitation of the sole of the foot of the non-paralysed side, and the phenomena of Raimiste.

Obstetrics and Gynaecology.

452. Mixed Tumours of the Uterus and Vagina.

W. SHAW (*Journ. Obstet. and Gynaecol. of the British Empire*, Autumn Number, 1928, p. 498) correlates the well known grape-like sarcoma of the cervix uteri with similar tumours of the corpus uteri and with certain of the vaginal sarcomata of children. All these are included under the heading "mixed tumours," by which are understood sarcomatous neoplasms, usually of special cytological characters, and invariably containing tissue elements (such as striped muscle cartilage, fat, bone, and elastic tissue, singly or in combination) which are foreign to the organ implicated. Mixed tumours of similar structure have been described in the kidney by Wilms, and in the prostate gland. Mixed tumours of the body of the uterus are the most of the three forms, thirteen cases only being on record. They occur in patients past the menopause and give rise typically to the same symptoms as cancer of the corpus uteri: the growths are polypoid, usually with a distinct pedicle. They are very vascular, liable to undergo necrosis and of a very high degree of malignancy. Mixed tumours of the cervix are more common, and give rise

to large growths possessing typical grape like vesicles, they are extremely malignant, death occurring shortly after extirpation without any extensive development of metastases. They cause irregular haemorrhage and discharge in patients, who are usually between 30 and 40 years old, and are easily diagnosed from naked eye appearances. Histologically the matrix of the tumour suggests oedema or myxoma, probably the tissue is similar to embryonal mesenchyme. A well preserved squamous epithelium usually covers almost completely even large tumours. Not all vaginal sarcomata in children belong to the group of "mixed tumours," but at least one quarter contain striated embryonic muscle fibres. Characteristically the tumours are multiple and attached to the vaginal walls, infiltrating the bladder, usually the patients are aged from 1 to 3 years. There is no satisfactory explanation of the origin of these "mixed tumours."

363. Post partum Haemorrhagic Amblyopia Treated by Transfusion.

A. FUCHS (*Med Klinik*, September 28th, 1928, p 1533) reports a case of post-partum amblyopia cured by transfusion. The patient, aged 29, had a severe haemorrhage after the birth of twins, she had had albuminuria before her confinement. Fourteen hours after delivery her visual acuity was greatly diminished, she could count fingers only at a distance of 40 inches, and could recognize friends only when they were standing close to the head. The papillae were pale, the vessels contracted, and the choroids greyish white. The transfusion of 250 c.c. of blood was followed by immediate improvement, and the patient was enabled to count fingers at a distance of 10 feet. Next day there was still greater improvement, the papillae were no longer blurred, the retinal oedema had disappeared, and the vision was 6/18. On the following day a further 250 c.c. of blood was transfused, and three days later the fundi appeared to be healthy, the formerly contracted vessels were of normal calibre, and the papillae were clearly defined. Six weeks after the confinement the papillae and obovoids were of the natural colour and the vision was normal, in the lower part of the left fundus alone did the vessels appear contracted. The field of vision showed a slight contraction in its upper part—25° for red, 30° for black. The author remarks that severe haemorrhage produces such changes in persons who are not entirely healthy, these sequelae were not observed during the war. The prognosis of this condition is very unfavourable, especially when it occurs immediately after delivery. One writer has observed 14 cases of amblyopia of this nature, 11 of these terminated in amaurosis, and in three patients the condition was bilateral. Local treatment, including massage, paracentesis, sclerotomy, and irideotomy, was of little effect.

364. Bleeding after Coitus in Cervical Cancer

ACCORDING TO H. HINSELMANN (*Zentralbl. f. Gynäk.*, September 22nd, 1928, p 2450) the bleeding after coitus which frequently constitutes an early symptom of cancer of the cervix uteri is one most commonly to tramatism involving an ulcerated carcinomatous area, in which the inflamed base is the site of inflammatory changes. It may also be caused by the detachment of fragments of carcinomatous epithelium. As proof of the latter mode of causation Hinselmann relates the case of a woman who, in spite of a two years' history of bleeding after coitus, had a cervix of which the surface was smooth and non-ulcerated, as shown both microscopically and by examination by the author's colposcope. The whole cervix, examined in serial sections, showed no trace of neoplasia, but in places fragments of carcinomatous epithelium were missing from areas in which the adjacent connective tissue showed no neoplastic invasion, but was the site of small round cell infiltration.

Pathology.

365. Blood Changes during Malarial Paroxysms.

OF the various suggestions as to the cause of the febrile attacks in malaria, J. A. SINTON, W. B. F. ORR, and B. AHMAD (*Indian Journ. Med. Res.*, October, 1928, p 341) consider that the most probable seems to be that it is a condition closely allied to the anaphylactoid shock seen after the parenteral injection of foreign protein. Some points of resemblance between these conditions are (1) a sudden onset of fever, followed by a fall by crisis, with profuse sweating, (2) a marked fall in blood pressure, (3) a diminution of the alkali reserve of the body, (4) a blood crisis of remarkable intensity, characterized by a leucopenia and a shift to the left of Arneeth's index (the haemoclastic crisis), (5) a diminution in the number of platelets in the peripheral blood, (6) an

increase in the rate of sedimentation of the red cells, (7) an increase in the blood sugar, (8) a diminution in the complement in the blood, and (9) acute enlargement of the spleen. Those points favour the theory that the malarial paroxysm is of the nature of an anaphylactoid shock, due to the sudden entry into the blood of foreign protein at the time of sporulation of the parasites. This protein may be derived from the parasite itself, from the erythrocytes altered by its action, or from malarial pigment. Widal, Abram, and Brissaud state that in the shock produced by foreign proteins there is a haemoblastia or colloidoclasia, with alterations in the surface tension, conductivity, viscosity, refractive index, etc., of the blood. To determine whether similar changes occur during malarial paroxysms the authors tested the serums of twenty patients suffering from benign tertian malaria and showing *P. vivax* in the peripheral blood. Changes similar to those recorded during anaphylactoid shock were found to occur in the surface tension and refractive index when the blood was collected at the time of the paroxysm. Tests for the presence of bilirubin in the serums gave in all cases a positive indirect van den Bergh's reaction, and its amount was found to be increased.

366. The Weil-Felix Reaction in Experimental Rocky Mountain Fever

H. MÜNTER (*Zeit. f. Hyg. u. Infektionsk.*, September 10th, 1928, p 124) states that guinea pigs, rabbits, and monkeys can be infected with the Rocky Mountain fever virus and with the virus of typhus, in addition, the Rocky Mountain virus is able to infect rabbits, whereas the typhus virus cannot do this. In order to gain some light on the relationship between the two diseases he has studied the Weil-Felix reaction in rabbits injected with these two viruses. He finds that rabbits infected intravenously or intraperitoneally with the Rocky Mountain virus may develop agglutinins to *B. proteus* X 19 up to a titre of 1 in 80 or even 1 in 160, rabbits inoculated with the typhus virus develop a titre of 1 in 160 to 1 in 320. If rabbits which have received one inoculation with the Rocky Mountain virus are re-inoculated with the same virus the titre to X 19 does not rise, but if they are given an injection of typhus virus, then the titre does rise. The author takes this as evidence that the antigens of the Rocky Mountain virus and the typhus virus are not identical, even though both are able to stimulate the formation (in different degrees) of agglutinins to *B. proteus* X 19. This dissimilarity in the viruses is supported by the fact that the inoculation of typhus virus into rabbits does not protect the animals against a subsequent injection of Rocky Mountain virus. It would appear, therefore, that, though in both infections the Weil-Felix reaction may be positive, the infecting viruses are different.

367. The Serological Differentiation of *Brucella abortus* and *Brucella melitensis*

J. VIDAL and R. ABELLA (*C. R. Soc. de Biologie*, October 26th, 1928, p 1271) have endeavoured to distinguish between *Br. abortus*, the causative organism of infectious abortion of cattle, and *Br. melitensis*, the causative organism of undulant fever. They made use of the method recommended by Domingo and Lopez, of suspending the organisms in a fluid containing bile, and of Fical and Alessandrini's method of heating the serum to 55°C for thirty minutes to destroy the non-specific agglutinins. The serums used came from aborting cattle, from rabbits immunized with heat-killed or formalized suspensions of *Br. abortus*, and from goats injected with living *Br. abortus*. The results showed no constant difference in the agglutinability of the two organisms, sometimes one agglutinated higher, sometimes the other, sometimes the bile suspension seemed to be a little more specific, and sometimes the normal suspension gave the better results. Obviously enough, both the serums from goats injected with *Br. abortus* agglutinated *Br. melitensis* to a higher titre than the homologous organism. The authors then tested 90 serums from cattle, having a titre of 1 in 200 or over, against fresh suspensions of the two organisms. Of these serums 41 agglutinated both organisms to about the same titre, 11 agglutinated *Br. melitensis* to a higher titre than *Br. abortus*, 16 agglutinated *Br. abortus* to a higher titre than *Br. melitensis*, 11 agglutinated *Br. melitensis* only, and 11 agglutinated *Br. abortus* only. From these results the authors conclude that serologically the two organisms are identical. In another paper (*ibid.*, p 1279) J. VIDAL reports a comparison of the agglutinability of the two organisms by 1 per cent lactic acid, which is said to agglutinate *Br. melitensis* but not *Br. abortus*. Working with 17 *melitensis* and 6 *abortus* strains, the author found that all the *abortus* strains and 10 of the *melitensis* strains were agglutinated, 7 of the *melitensis* strains failed to agglutinate. He concludes that this test is likewise unable to distinguish between the two organisms.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine

568

Cerebral Cysticercosis

P. SCHMITE (*Ann de Méd*, October, 1928, p 288) believes that, though not a frequent disease, cerebral cysticercosis is not so rare as is thought. In this disease the parasite often assumes abnormal forms. Sometimes it is destitute of head or hooks, at other times it is branched and complicated, attaining a length of 20 to 25 cm, being then known as the *Cysticercus racemosus*. The essential lesions of the disease are of two types, meningeal and cystic. The sites of the former are obliquely the base of the brain and the posterior spinal region. The basilar lesions are intense, the meningitis presents a lardaceous, gummatous appearance, is irregular, and always very thickened (in places to 3 to 5 mm), simulating chronic tuberculous or syphilitic meningitis. The spinal lesions are more important. They cause a lepto meningitis, mainly localized on the posterior surface of the cord in the cervico dorsal region. This meningitis, characterized by slight thickenings very different from those of the basilar type, shows in places small whitish swellings in which can be seen cystic vesicles. Cystic lesions are much rarer, and are characterized by the formation of small cysts on the external surfaces of the hemispheres or in the cerebral parenchyma. Only the former can be surgically removed. Other lesions are vascular changes, especially in the basilar and Sylvian arteries, simulating syphilitic endarteritis, and, in ventricular cysticercosis, a granular opendymitis and hydrocephalus. Clinically, three varieties of this disease can be distinguished—the cystic, meningeal, and mental, anatomically, there are two types—the ventricular, and the medullary and spinal meningeal. The cystic form, a veritable tumour, is accompanied by the usual signs of intracranial hypertension, it is very frequently marked by convulsive (epileptic) crises and a general headache with crises of vomiting. The meningeal form is characterized by sensory, motor, and mental troubles. All the cranial nerves, especially the ocular, are affected. The mental type shows symptoms of depression, troubles of memory, and disorientation in time and space. The ventricular forms are localized in the lateral and the third and fourth ventricles, particularly the last, two distinguishing symptoms are abnormal attitudes of the head and increased cephalalgia, with vertigo and vomiting on moving the head. The diagnosis of cerebral cysticercosis is extremely difficult. Blood eosinophilia may be present, the cutaneous and subcutaneous reactions, the precipitin diagnosis of Heig and Lisbonne, and complement fixation tests are the more important diagnostic criteria. Lumbar puncture is the chief diagnostic proceeding, especially in meningeal cases. The fluid is clear and slightly under pressure, with an albumin content of 0.4 to 0.75 gram, positive Pandy and Wetschbiold reactions, and a cell count of 50 to 300 (chiefly lymphocytes). The colloidal benzoin test is positive in the first ten or twelve tubes. Those results, coupled with negative bacillary and Wassermann tests, distinguish the disease from tuberculous and syphilitic meningitis and from cerebral abscess and tumour. The prognosis is always grave. Medical treatment appears useless, though some authors report benefit from etheral extract of male fern given in large doses over a long period. X-ray and radium therapy seems to have benefited some cases, and merits a trial. Surgery is applicable only in the cystic forms.

569

Syphilis and Tuberculosis

L. S. T. BURRELL (*Brit Journ Venere Dis*, October, 1928, p 290), in considering syphilis in relation to the etiology and diagnosis of tuberculosis, points out that (1) since bacilli are almost invariably present in the sputum in chronic pulmonary tuberculosis, their absence on repeated examinations indicates the possibility of the condition being non-tuberculous in spite of suspicious physical signs, (2) signs of fibrosis at the root of the lungs spreading towards the bases, and with but few constitutional symptoms, are consistent with syphilis and are not common in tuberculosis, (3) a considerable extent of tuberculous disease may exist without much dyspnoea, while it is the most prominent symptom in syphilis, (4) a positive Wassermann reaction does not necessarily imply syphilis of the lung, and (5) improvement on antisyphilitic treatment confirms the diagnosis of syphilis. Burrell concludes that syphilis of the lungs is seen chiefly either as a peribronchial fibrosis resembling chronic fibroid tuberculosis, or as a mediastinal gumma producing effusion

and resembling a neoplasm. S. R. GROVE (*Ibid*, 1928, p 293) considers that positive Wassermann tests in known tuberculous patients should be repeated with cholesterolized and non-cholesterolized antigens and that positive complement fixation reactions in syphilitics should be accepted with reserve. The surgical tuberculosis group of bone and joint diseases presents the greatest difficulties in distinguishing between the two diseases, especially when there are no discharges from which pus can be obtained for examination. Grove calls attention to the need of a reliable serological test for tuberculosis, since, while the sedimentation test appears to be the best of the non-specific ones, it is doubtful how far it could be used as a means of differential diagnosis between syphilis and tuberculosis.

570

Antityphoid Inoculation

D. OTTOLENGHI and G. BROTTU (*Bull Sci Med*, July-August, 1928, p 213) record their observations on antityphoid inoculation of rabbits and healthy adult men who had not had typhoid fever, their conclusions being as follows. The oral administration of antityphoid vaccine gives experimental animals a considerable degree of immunity against typhoid and paratyphoid infection. This immunity, however, is always considerably less than that obtained by subcutaneous injection of the vaccine. The state of immunity is denoted satisfactorily ten days after completion of the inoculation, and persists though gradually becoming less marked, for another two months. The immunity following oral vaccination in animals is accompanied by the appearance of bactericidal bodies and probably lysins. Bactericidal bodies and a slight allergic state are also found in human subjects who have been inoculated against typhoid fever. Inoculation by the nasal route is also followed by the appearance of abundant agglutins in the blood. Animals which have been inoculated by any of these three methods and have resisted a control inoculation may nevertheless remain typhoid carriers for some weeks. Although the authors' experiments on man are not sufficiently conclusive as to the value of oral antityphoid inoculation, they are encouraging, even if the results are less successful than those obtained by the ordinary subcutaneous method.

Surgery.

571

Leucoplakia of the Urinary Tract.

W. E. KEANE and G. M. DENNIS (*Urol and Cut Rev*, September, 1928, p 589) record an illustrative case with a review of the literature, and come to the following conclusions. Leucoplakia of the urinary tract is not so uncommon as the few reported cases (81) indicate. The condition is a true metaplasia, a degenerative alteration of one of the primary types of tissue. Renal leucoplakia is probably more common in reality than vesical, because vesical leucoplakia is more easily diagnosed. The etiology is not understood, but the general view is that it is the result of chronic infection. It is very likely that syphilis plays an important part. Some writers believe that it is congenital and that misplaced test cells are at fault. The condition may occur at any age but the onset as a rule is in the late thirties or early forties. It probably occurs more often in males than in females. The only pathognomonic symptom is the passage of membrane, from which the diagnosis is made by microscopical examination. Persistent colic is usually associated with this. Leucoplakia does not as a rule respond to irrigations and instillations, but resection, radium, and electro-desiccation are the only effective methods of treatment.

572.

Cysts of the Spleen

H. GATERSLEBEN (*Deut Zeit f Chir*, October, 1928, p 139), who records an illustrative case, states that Lubarsch distinguishes two groups of cysts of the spleen and splenic capsule. The former consists of multiple small cysts situated just beneath the capsule, and the latter of large and usually single cysts frequently giving rise to symptoms during life. The diagnosis of splenic cysts is difficult, since the small cysts usually escape notice during life while in the case of the large cysts the symptoms may be general, such as anorexia and fatigue, and local, such as pain and swelling in the left hypochondrium, and digestive disturbances due to local peritoneal irritation. Fever may occur as the result of septic complications. These symptoms may develop

insidiously, but often appear with remarkable suddenness. A ray examination is of value, especially in cases where there is more or less marked calcification. Treatment, which must be surgical, is only required in the case of large cysts. Marsupialization and resection of the cyst wall should not be employed unless the cysts are of enormous size and are accompanied by dense adhesions. The best treatment is splenectomy. Gatersleben's patient was a woman, aged 34, who had suffered from weakness, loss of flesh, and pain in the back and hypochondrium for two months. An x-ray examination showed appearances resembling those of a calcified hydatid. The operation, however, proved that the condition was a calcified splenic cyst. Splenectomy was performed and recovery followed. This is said to be the first time that a splenic cyst has been diagnosed by x-rays.

473. Chronic Gonorrhoeal Cowperitis.

ACCORDING to E. SKLARZ (*Derm. Woch.*, September 29th, 1928, p. 1380) all authorities are agreed as to the importance of infection of Cowper's glands, which are much more frequently involved in gonorrhoea than is generally supposed. The following three groups of chronic gonorrhoeal Cowperitis can be distinguished: (1) Cases in which the first portion of urine is clear or only slightly turbid. The flocculi floating in it contain mucus and only a few leucocytes. The threads which come from Cowper's glands usually contain no epithelial cells, but occasionally groups of gonococci lying in the mucus and enclosed in the leucocytes. The patients have a watery discharge, and show inflammation of Cowper's glands both on rectal palpation and on endoscopic examination of the opening of the glands into the urethra. (2) Cases with neuralgic symptoms. The patients complain of pain on defecation, or after standing or sitting for a long time, and occasionally suffer from stabbing pain in the rectum. The urine may be quite clear and free from filaments, and such cases are frequently wrongly diagnosed as hysteria. (3) Cases in which violent relapses occur. The gonorrhoeal infection lies dormant in Cowper's glands, and as the result of riding or some excess is roused into activity. The treatment, which varies according to the clinical findings, consists in antiseptic injections, passage of bougies, and external massage of the affected glands. Hot hip baths and diathermy are also of value, and vaccine treatment may be tried.

474. Interpectoral Cellulitis

A. NUÑEZ (*Arch. de med. cir. y esp.*, October 13th, 1928, p. 412), who records two illustrative cases, in men aged 26 and 56 respectively, states that little attention has been paid to cellulitis and acute abscess arising in the space between the pectoralis major and the clavi-coraco-axillary aponeurosis of Mochet. The condition is the result of a wound, boil, eczema, whitlow, or other lesion in the area drained by the lymphatic glands in this space. The earliest symptoms are severe pain in the root of the arm with high fever, which, after being intermittent, becomes continuous, and is accompanied by profound constitutional disturbance. At first the pain and functional weakness shown by difficulty in abduction of the arm through contracture of the pectoralis major constitute the only local symptoms. There is no change in colour of the skin of the anterior region of the thorax or arm, no oedema or supplementary circulation, the skin is not painful, and moves freely over the deeper structures. In a few days, however, the anterior wall of the axilla presents a deep-seated swelling extending upwards to the shoulder and downwards to the lower border of the pectoralis major. Examination of the blood shows the characteristic picture of an acute abscess. Treatment consists in early and free incisions under general anaesthesia, one being made a few centimetres below the clavicle and the other below the lower border of the pectoralis major. The arm should then be kept in a position of extreme abduction by a Thomas's splint.

475. Primary Tumour of the Lung

M. W. MARSHMAN (*Nederl. Tijdschr. v. Genees.*, September 15th, 1928, p. 4498), who has seen fifteen cases of tumour of the lung in the last two years, concludes that it is commonest in males, only one of his patients was a woman. It is exceptional in young persons, and usually occurs in the middle aged and elderly, the ages of his patients ranged from 43 to 61. Marshman advises that the existence of primary tumour of the lung should be suspected when a patient about the age of 40, who has previously had good health, develops an obstinate cough with occasional blood in the sputum, and complains of pain behind the sternum with shortness of breath, which is increased by movement, or of neuralgic or rheumatoid pains in an arm or along the intercostal nerves without any physical signs being found to explain the condition.

Therapeutics

476. Auto haemotherapy in Herpes Zoster

ON the ground that no great advance in the treatment of herpes zoster has been made until recently, B. B. BEESON (*Arch. Derm. and Syph.*, October, 1928, p. 573) advocates auto-haemotherapy in this disease. The method, first employed five years ago by Spillmann and Raspiller, consists in the withdrawal of blood as for a Wassermann test and its injection into the gluteal muscles, preferably into the upper and outer quadrant. The amount varies from 5 to 20 c.c., the usual dose being 10 c.c., for children half this amount is the rule. Injections may be repeated every two, three, or four days, the number in herpes zoster being two to six. The procedure appears to be free from any serious after effects, except for slight pain at the site of injection, or a mild febrile reaction in a few cases. Several cases are cited from the literature on the subject which responded favourably to auto-haemotherapy, and Beeson reports seven further cases in which this method, the sole treatment employed, produced excellent results. In two of these cases a single injection of 10 c.c. entirely relieved the pain and aided in quickly healing the cutaneous lesions. According to Wintz the various theories concerning auto-haemotherapy are based on sensitization and desensitization, and he himself believed that the leucocytosis induced by the treatment plays an important part. Some consider that this treatment should be considered a form of protein therapy, and Raspiller compared its action to that of peptone. From their results in eleven cases Mouton and Rachelet concluded that auto-haemotherapy produced a haemoclastic reaction, which was followed within a hour by a hyperleucocytosis. Piffard expressed the belief that the injected venous blood is slowly absorbed by the lymphatics, and suggested that this passage through the lymphatics may produce favourable defence reactions. Louste, Thibaut, and Barhier agreed with Spillmann that auto-haemotherapy may be classed with the methods of non specific desensitization.

477. Antigen Therapy in Hodgkin's Disease.

A. WALLHAUSER and J. M. WHITEHEAD (*Amer. Journ. Surg.*, September, 1928, p. 229) give results of a method of treatment of Hodgkin's disease by means of autogenous, bacteria free extracts made from the specific lesions of the disease. This extract was given subcutaneously in small and usually increasing doses over a period of several months. Of five cases treated, improvement was shown in all, with complete disappearance of all clinical symptoms in two cases. The extract was made from the more cellular masses and not from hard dense nodes, care being taken to maintain the sterility of the finished product, which was injected at a point distal to the more prominent lesions. The dosage began with 0.1 c.c., and increased by a similar amount to a maximum of 0.5 c.c. The first sign of improvement was seen in the specific lesions, which became smaller and softer, the temperature gradually reached the normal, and symptoms of nausea, dyspnoea, and asthenia were relieved. Later, only fibrous nodules were left, which disappeared after several months, the cachexia was gradually reduced, and in two cases there was a most striking gain in weight. The authors state that the injections should be continued every other day until definite improvement is noticed, the interval is then increased, weekly injections being given for three or more months. The best results were obtained when the dose was kept well below the toxic amount, and when the injections were employed regularly over a prolonged period of time, an occasional rest period of one or two weeks being sometimes advisable.

478. Sodium Sulphocyanate in Hypertension

A. G. SMITH and R. D. RUDOLF (*Canadian Med. Assoc. Journ.*, September, 1928, p. 288) report favourably of their experience in the use of sodium sulphocyanate in high blood pressure. The drug is an alkaline, white, crystalline powder, very soluble in water or alcohol, in aqueous solution daily doses of 15 grains are usually tolerated over a period of at least three weeks. The sulphocyanates are normally present in dilutions of 1 in 10,000 in the saliva, tears, and urine, when given by the mouth the content in the saliva and urine is markedly increased, and persists for several days after administration is discontinued. In persons with normal blood pressure the systolic figure became lower by from 15 to 30 mm. in one week following 5 grain doses thrice daily after meals. In patients with abnormally high pressure similar effects resulted from 5 grains administered either once, twice, or thrice daily, a fall, especially in the systolic figure, occurring with usually no change in the cardiac rate. In those with much kidney damage or arterio-sclerosis a

similar effect was produced, though to a less extent. Notes of five cases are recorded, four patients being women, but it is stated that equally good results were observed in men. The drug has a sedative effect and is often mildly hypnotic. It would appear that a dosage of 2½ grains twice or thrice daily is sufficient to produce the desired effects, while it is pleasant to take in an aromatic mixture.

479

Iodine in Hyperthyroidism.

L. Dautrebande (*Presse Méd.*, October 27th, 1928, p. 1361) recalls the successive rises and falls in favour of iodine in the treatment of exophthalmic goitre since 1820. He attributes the disfavor into which iodine medication fell from 1910 to 1920 largely to Kocher's description of symptoms of hyperthyroidism appearing after iodine therapy in cases of colloid goitre showing indurated nodules, and even in cases of simple adenoma—the so-called iodine-basedow syndrome. Since 1920 many authors, especially in America, have advanced the view that iodine therapy, though useful in true exophthalmic goitre, is contraindicated in toxic adenoma. Dautrebande claims to have shown by his researches in connection with the report that the use of iodine in toxic adenoma, at any rate in Belgium, has been well proved, and he suggests that the contrary results noted in America and Switzerland are due to climatic differences and have no general application. Dautrebande uses a solution containing 10 grams of iodine and 20 grams of potassium iodide in 100 grams of water, he considers that it is of the utmost importance to keep a record of basal metabolism and to increase the dose after each rise of the rate. He disagrees with the view that the action of iodine is necessarily transient and that prolonged treatment is impracticable. In his experience the giving of the minimum effective amount in divided doses counteracts the rapid excretion of the drug in the urine. He quotes a case of exophthalmic goitre where improvement was not obtained till 5 drops of the solution were given over a half hour (twenty doses in twenty-four hours). In this case the patient was intelligent and used to measure his own doses. He claims that treatment by divided doses over a long period (several months, or even years when the patient is unwilling to have an operation) eventually puts the patient in a much better condition for surgical treatment than the method of giving iodine only for a short time immediately prior to operation and that by the former method the basal metabolism can be maintained at a normal level for long periods.

Ophthalmology.

480.

Diathermy in Ophthalmology

A. MONBRUN (*Journ. de med. et de chir. prat.*, June 10th, 1928, p. 385) maintains that both medical and surgical diathermy may be of great value in ophthalmology. Owing to its numerous physiological effects and its penetrating action, medical diathermy may be of use in affections which prove refractory to ordinary treatment. Monbrun has employed it with success in atonic ulcers of the cornea, neuro-paralytic keratitis, and follicular conjunctivitis. Its analgesic action is particularly noticeable in the neuralgia following ophthalmic zoster. At present the method appears to be contraindicated in intraocular affections. Surgical diathermy, or diathermo-coagulation, is the method of choice for clearing out the orbital cavity before fitting in an artificial eye. It is also suitable for the treatment of tumours and chronic processes attacking the lids and ocular conjunctiva, such as palpebral epithelioma, xanthelasma, sties, ectropion and entropion, trachoma, pterygia, palpebral conjunctivitis, tubercles, and hernia of the iris or vitreous. Monbrun adds that it must be remembered that faults in technique may entail necrosis of the lids and severe damage to the eyeball.

481

Voluntary Extrusion of the Eyeball.

H. FERRER (*Rev. oto-neuro-ophthalmologica*, September, 1928, p. 403) records the unique case of a lad, aged 19 who had always had prominent eyes, and from the age of 5 or 6 had acquired the faculty of projecting his eyes out of their sockets to the extent of 9 millimetres, and keeping them in that position for some minutes without any inconvenience. The return of the eyeball to its normal position was also accomplished readily. These movements of propulsion and retraction could be performed in both eyes simultaneously, or first in one and then in the other, in which case the eye which was not pushed forward was slightly closed so that the eyelids could keep it in the orbit. The phenomenon was due to the fact that the boy possessed the faculty of contracting the oblique muscles, which push the eye forwards, at the same time that he relaxed the recti, which retract it,

while he kept his eyes wide open. The eyeballs then, being left to the action of the oblique muscles, passed through the palpebral fissures and were more or less rapidly extruded according to the patient's wishes. When more than half of the eyeball had left the orbit the orbicularis was contracted behind its equator, and the eye was thus held in position. To make the eye return to the orbit he first relaxed the orbicularis and then the oblique muscles. The visual acuity, accommodation, and fundi were normal, but there was a divergent strabismus of 20 degrees. Ferrer is of opinion that a continuation of the practice would in a few years produce irreparable loss in the optic nerve and retina.

482.

The Pulse during Operations on the Eye.

E. MARX (*Neurol. Tijdschr. v. Geneesk.*, October 20th, 1928, p. 5189), as the result of observations on the pulse in thirty-nine operations for strabismus and cleft enucleations, comes to the following conclusions: (1) In operations on the external ocular muscles changes frequently occur in the pulse, the rate, volume, form, and dicrotism being affected in order of frequency. (2) As a rule the pulse rate diminishes, but sometimes it shows an increase. The volume of the pulse usually increases, while the dicrotism generally shows little change. (3) The symptoms described must probably be regarded as reflexes the paths for which cannot at present be determined with certainty.

Obstetrics and Gynaecology.

483

Local Anaesthesia for Abdominal Caesarean Section

TREX (*Zentralbl. f. Gynäk.*, September 22nd, 1928, p. 2485) states that local anaesthesia in abdominal Caesarean sections is regarded as being fraught with such advantages both for mother and child that at Zürich it is given as a routine, exception being made only in cases of eclampsia or of patients with deficient mental development. He records an eight years' experience of 353 sections, of which 281 were performed under local anaesthesia. The percentage of live births was considerably larger after local anaesthesia, although this group included not only the whole of the cases of placenta praevia and premature placental detachment but also a large percentage of cases in which labour had continued for considerable periods in the presence of pelvic contraction. The cases of general anaesthesia included 5 of post-operative pneumonia, which was absent in the much larger group of local anaesthesia. All save one of 88 placenta praevia patients operated on under local anaesthesia survived, and a series of 20 cases of Caesarean section in subjects with decompensated heart lesions was without mortality. The better maternal results are in part to be ascribed to preservation of uterine tone, which is increased by the adrenaline in the infiltrating solution, to the small degree of bleeding from the uterine incision, and to the consequent facility of uterine suture, in the series recorded tamponage was never necessary, atonic post-partum bleeding was never noted and subsequent pregnancies and deliveries were normal in the 10 per cent of patients who conceived subsequently.

485

Diathermy of the Thyroid for Uterine Haemorrhage.

G. TRAVERSO (*Ann. di Ostet. e Ginecol.*, September 30th, 1928, p. 1099) in a preliminary communication reports satisfactory immediate results from treatment of excessive uterine haemorrhage by application of the diathermic current to the region of the thyroid and parathyroid glands. Having found that in three healthy young subjects with normal menstruation the treatment described was followed by oligomenorrhoea (in one patient combined with menstrual retardation), and that in three other patients suffering from dysmenorrhoea associated with morbid functional symptoms this treatment gave rise to scantier menses without pain or sympathetic phenomena, Traverso tested the effect of thyro-parathyroid diathermic applications in 52 women suffering from metrorrhagia or menorrhagia. These comprised 25 cases of metrorrhagia, 11 of uterine myoma, 3 of parenchymatous metritis, 11 of adnexal inflammation and 2 of metastasis ascribed to uterine retroversion. In all the author found that diathermy led to cessation of haemorrhage but the cases are too recent to permit of a description of the later results. Of the cases classified as metrorrhagia haemorrhage the majority occurred in subjects about the age of puberty—a time when a particularly good response is said to follow diathermic application. The strength of the current employed was, as a rule, half to one and a half amperes, and large dorsal and small cervical electrodes (7 by 4 cm.) were used,

the applications, repeated on successive or alternate days, lasted up to half an hour or even longer. In the hands of other observers (*Arch f Gynaek*, 1924, p 310) modification of thyroid activity by α radiation has proved successful in the treatment of excessive uterine haemorrhage of puberty.

385 Cystoscopy in Carcinoma of the Cervix.

A. A. GEMMELL (*Journ Obstet and Gynaecol of the British Empire*, Autumn number, 1928, p 465) describes his cystoscopic findings in 111 cases of carcinoma of the cervix, and discusses the practical value of this procedure in this connexion. Thirty nine of the cases were clinically judged to be operable. The chief findings, enumerated in ascending order of gravity, are (1) bulging of the bladder floor, (2) circulatory changes—namely, dilatation of vessels, appearance of new vessels, petechial submucous haemorrhages, and definite haemorrhagic suffusion, (3) transverse ridging and furrowing of the bladder wall, (4) oedema, diffuse or bullous; (5) desquamation, and (6) malignant invasion. Gemmell concludes that while cystoscopy is unnecessary in clinically inoperable cases, in the borderline case it is of great value and may be the deciding factor, it affords a means of assurance that there is no extension of the growth forwards which has escaped detection on bimanual examination. He finds that bulging of the bladder wall is mechanical only, and that circulatory changes are a part of the pelvic hyperaemia associated with the disease, transverse ridging, on the other hand, is a cystoscopic finding which denotes the limit of operability. Bullous oedema is associated with neoplastic invasion of the bladder wall or an extremely near approach thereto. Gemmell's conclusions are in general accord with those of foreign workers; he points out that the neglect of cystoscopy in cancer of the cervix is partly explicable by the increasing adoption of radium as against operative treatment, and partly by Schauta's denial of the significance of the cystoscopic picture. Schauta, however, extended the limits of operability far beyond the majority of surgeons, and mostly performed vaginal extirpation.

Pathology.

386 The Precipitating and Protective Powers of Anti-anthrax Serum

A. SORDELLI, C. HARISPE, and P. BELTRAMI (*C R Soc de Biologie*, November 9th, 1928, p 1423) recommend for the preparation of anti-anthrax serum the prolonged injection of horses or mules with capsulated strains of *B anthracis* cultivated on serum agar. Serums prepared in this way have a marked precipitating power. For use in the diagnosis of anthrax the authors find that if the extracts of the organs are prepared by maceration in the cold with carbolized saline the results are very much better than if they are made by boiling, as in the usual Ascoli thermo-precipitation method. The amount of precipitinogen in the "cold" extract is often ten times as great as that in the extracts made by heating. The dilution of the serum should be with normal serum, since they find that the use of distilled water causes a flocculation of the englobulins and at the same time of the precipitins. A. SORDELLI, P. BELTRAMI, C. HARISPE, and C. FRANCESCHI (*ibid*, p 1428) find that serums prepared in the way already described have a neutralizing and a protective power. The neutralizing power can be illustrated by mixing the anthrax culture and the serum *in vitro*, the protective power can be shown by the subcutaneous or intraperitoneal injection of guinea pigs and by the intraperitoneal and intravenous injection of rabbits with the serum, followed later by injection of the bacilli. The serum must be injected before the organisms, when given at the same time as, or later than, the bacilli it had—under the conditions of the experiment—no protective effect. Dilution of the serum with nine times its volume of distilled water saturated with CO_2 precipitated the englobulins leaving the albumins and pseudo-globulins in solution. The protective antibodies are all contained in the englobulin fraction. Since the englobulins represent only one fifth of the proteins in the serum, it is possible to concentrate the antibodies considerably by this means.

387 The Sugar Content of the Skin

E. URBACH and G. SICHER (*Wien med Wchns*, October 25th, 1928, p 1481) believe that the role of the skin in carbohydrate metabolism and sugar storage must be of considerable importance, in view of the fact that it weighs three times as much as the liver and normally contains a higher percentage of sugar than muscle (dog skin 67 mg per cent, muscle 54 mg per cent, rabbit skin 117 mg per cent, muscle 55 mg per cent). In a series of preliminary experiments they

estimated the sugar content of the skin by an electrical intra-vital method in a number of animals and in man, and compared it with the blood sugar curve, they found that the ratio was normally fairly constant for each group of animals examined, but varied in different species. Thus in human and monkey skin the sugar value was about half the blood sugar, in the dog about two thirds, while in the rabbit, guinea pig, and rat the two values were about equal. The amount of carbohydrate in the diet also normally has some effect on the skin sugar content. Successive estimations in normal human subjects and the sympatheticotonia after an intake of 100 grams of glucose showed that the maximum skin sugar value was reached after one hour, it then fell more slowly than the blood sugar, but had invariably returned to the initial value in four hours, the two curves running to some extent a parallel course. In pancreatic diabetes the skin sugar figure after glucose did not reach its maximum for three hours, and had not returned to the resting level in four hours. It is suggested that this prolonged storage of sugar in the skin may account for the susceptibility of diabetic patients to skin lesions. The administration of large doses of insulin showed that the skin sugar was only mobilized up to a point, and remained relatively high even during hypoglycaemia. In a number of patients with skin diseases examined four types could be distinguished: (1) blood and skin sugar curves normal, (2) blood and skin sugar curves characteristic of diabetes, (3) skin and blood sugar curves suggesting latent diabetes—normal fasting blood sugar, glycosuria absent, sugar tolerance diminished, some mild cases gave a diabetic skin sugar curve with a normal blood sugar curve, and (4) blood sugar curve indicating sympathetic endocrine disturbance—the fasting blood sugar normal, after glucose there was a rapid rise to a high maximum with an equally rapid fall, while the skin sugar curve remained normal.

388 Bacillary Types in Human Bone and Joint Tuberculosis

A. S. GRIFFITH (*Journ Path and Bact*, October, 1928, p 875) has determined the type of the infecting virus in a new series of 132 cases of bone and joint tuberculosis, of these, 111 proved to be of human type and 21 of the bovine type. Among the human viruses there were two dysgonic strains, and among the bovine viruses there were two strains of attenuated virulence. Summarizing all the cases in Great Britain that have been typed by the Royal Commission, Eastwood and Griffith, and the author, he obtains altogether 598 cases. Of these, 20.5 per cent were infected with the bovine bacillus, the remainder with the human bacillus. The proportion of bovine infections is closely dependent upon the age of the subject—the younger the patient the greater the proportion of bovine infections. Thus, under 5 years of age the proportion of bovine infections was 32.8 per cent, from 5 to 10 years 24.5 per cent, from 10 to 15 years 12.1 per cent, from 15 to 25 years 10.5 per cent, and over 25 years 0 per cent, no case of bovine infection was in fact observed in patients more than 23 years of age. Examining the distribution of human and bovine infections among the different joints, he obtained evidence to suggest that bovine infections are commoner in the spine than in the joints of the leg. This he considers is probably due to the fact that the vertebrae are sometimes infected directly from the mesenteric or other abdominal lymphatic glands, since 82 per cent of cases of primary abdominal tuberculosis are of bovine origin, this would explain why a higher proportion of bovine infections are encountered in the spine than in other joints. Finally he brings evidence to show that bone and joint tuberculosis may result from either a respiratory or an alimentary infection, the former being the commoner.

389 Etiology of Coeliac Disease.

WITH a view to obtaining information about the determining causes of coeliac disease A. MONCRIEFF and W. W. FARNS (*Arch Dis in Child*, October, 1928, p 257) have investigated a number of cases in children up to the age of 4 years. Working with very small quantities of blood, the normal figure of the blood fat was established, and attention was then paid to coeliac disease in which large, bulky, fat-containing stools are characteristic, but no organic disease has yet been described. In these children, who are much under weight and are under developed, the blood fat was very high, sometimes as much as ten times the normal. The authors advance the theory that coeliac disease is possibly not due to a malabsorption, but rather to a malutilization, and that the difficulty of fat metabolism is comparable with the defective utilization of sugar in diabetes. It is claimed by other workers that the fat found in the faeces in coeliac disease is due to a re-excretion of blood fat, and the authors suggest that the large quantities present are due to a leakage of this blood fat.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

490 Inoculation of Pirquet Negative Persons with B C G

J. H. INUBACK (*Idiosyncrasy of Normal Infector*, October 15th, 1923, p. 945) has, since May, 1926, inoculated 726 Pirquet negative persons up to the age of 30 with Calmette's B C G culture of living bacilli. This vaccine was given by subcutaneous injection, and as the original dose of 0.2 mg frequently provoked local abscesses it was reduced to 0.05, and in some cases even to 0.02 mg. Among the 726 persons thus treated were 89 nurses whose Pirquet-negative reaction when they first joined the author's hospital showed that they were in grave danger of contracting tuberculosis from the patients they were about to nurse. Five of these nurses were inoculated in October, 1926, and their treatment in this way was so far unsatisfactory in that they had already nursed tuberculous patients three or four months before they were inoculated. There were 44 nurses in 1927 and 40 in 1928 who, as soon as they were found to be Pirquet-negative on entering hospital for the first time, were inoculated with B C G. For the next month or six weeks they were kept away, so far as was possible, from tuberculous cases. Only in 2 of these 89 cases did signs (pleurisy) of tuberculosis subsequently develop. One of these nurses was among the five who had been inoculated in 1926, and who had been exposed to infection for some months before the inoculation. The other nurse had been inoculated only for a month when she developed pleurisy. In the same two years, 1927 and 1928, there were 30 nurses who were Pirquet-negative when they joined the hospital, but who refused to be inoculated. Eight of these nurses (27 per cent) subsequently developed signs of tuberculosis after having been in attendance on tuberculous patients. With regard to the nurses who were Pirquet-negative when they joined the hospital in 1924, 1925, and 1926 and who were not inoculated with B C G, it was found that 16 per cent of them had subsequently developed signs of tuberculosis. In none of the 726 Pirquet-negative persons inoculated with B C G did this treatment provoke illness, but in as many as 53 cases abscesses formed at the site of injection. They were some what tender, but the discomfort was purely local, and there was no evidence of general constitutional disturbances. In eight cases glandular nodes were inoculated with the pus from these abscesses, and none of these animals developed tuberculosis. The most effective remedy for these abscesses was quartz lamp light treatment, which cured the largest abscess in a week. Heimbeck adds that the exclusion of Calmette's system (giving newborn babies B C G by the mouth) to the subcutaneous injection of Pirquet-negative adults with this vaccine is the more important since only a minority of human beings in an ordinary civilized community are infected with tuberculosis during childhood. He records his own mass Pirquet tests in support of this opinion, which, he admits, is not generally accepted.

491 Myocarditis

B. J. CLAWSON (*Inner Heart Journ.*, October, 1928, p. 11) has made a study of the gross and microscopical features of the myocardium in 429 patients dying from cardiac failure. These observations were made in order to determine the conditions under which a diagnosis of myocarditis might be justifiable. Among 178 hearts from subjects of rheumatic and bacterial valvular diseases acute myocarditis with proliferative inflammation occurred frequently in non-rheumatic endocarditis (80 per cent), in recurrent rheumatic endocarditis (65 per cent), and in subacute bacterial endocarditis (73.5 per cent), but the myocardium associated with old valve defects and with adherent pericardium showed this type of inflammation in much smaller proportion (about 20 per cent). The myocardium was studied in 106 cases of syphilitic aortitis. In only 11 of these was proliferative inflammation observed, while myocardial fibrosis of the atrophic type was also found only eleven times. Hypertensive hearts made up 139 of the 429 cases examined. Cellular proliferation or exudation was never found in these hearts except in the presence of infarction. Severe degrees of coronary sclerosis were found in 56, and in a majority of these death had occurred suddenly from coronary narrowing. Only 20 of the hypertensive hearts showed extensive myocardial fibrosis while in 60 there was no fibrosis. Such fibrosis as was found appeared to result from myocardial anæmia following narrowing of the coronary arteries. Failure, the sequel of right ventricular hypertrophy and dilatation, was present in only

4 of the 429 cases, and in each slight proliferative fibrosis was seen. The author concludes from this work that the extent of the myocardial injury, as shown by anatomical changes, rarely appears to be sufficient to bring about cardiac failure, and that the conditions usually diagnosed as acute or chronic myocarditis cannot be demonstrated to be inflammatory processes.

492 Dry Bronchiectasis

R. RAGUZ (*Arch. de med. et y esp.*, November 3rd, 1928, p. 492), who records an illustrative case, states that the principal feature of bronchial dilatation is the association of profuse expectoration with the signs of a cavity. In many cases the fluoroscopic screen or x-ray plate confirms the clinical findings, but in others the physical signs suggestive of bronchial dilatation are negatived by x-ray examination. Raguz's patient was a girl, aged 20, who had suffered from frequent hæmoptysis for several years. Examination of the sputum was negative for tubercle bacilli, and nothing to indicate a broncho-pulmonary lesion was found on x-ray examination. After two injections of lipiodol, however, bronchial dilatations were found which accounted for the hæmoptysis. The therapeutic action of lipiodol was also illustrated by complete cessation of the hæmoptysis and improvement of the general condition.

493 Familial Anæmia with Splenomegaly in Infancy

I. AURICCHIO (*La Pediatria*, October 1st, 1928, p. 1023) publishes a dozen cases of anæmia associated with splenomegaly in infants. The chief interest of these cases lay in the fact that they were familial in type. The author failed to find any of the ordinary causes of infantile splenic anæmia, such as malarial parasites, sepsis, syphilis, or tubercle. It was noted that the first sufferers in the family were the older ones, while in the younger ones the condition appeared much earlier in life. Auricchio suggests that possibly in one or other of the parents there is a latent pathological condition which affects the normal formative process of the hæmopoietic organs in the infant.

Surgery.

494 Pre-operative Treatment of Graves's Disease.

G. L. ADAMSON and A. I. CAMERON (*Canadian Medical Assoc. Journ.*, October, 1928, p. 420), with the co-operation of the Medical Research Committee of the University of Manitoba, made a series of tests which show that vitiodum a preparation of iodized jecoleic acid incorporated with a vitamin concentrate from cod liver oil, has a value at least equaling that of Lugol's solution in the pre-surgical treatment of Graves's disease. Vitiodum is put up in gelatin capsules, each representing 275 units of vitamin A and not less than 75 units of vitamin D, together with iodized jecoleic acid containing 0.03 gram of available iodine, the equivalent of that present in 10 minims of Lugol's solution. In order to ascertain which of the constituents was responsible for two similar preparations in gelatin capsule form, one having the exact dosage of vitamins A and D contained in the vitiodum capsules and the other having the equivalent amount of iodized jecoleic acid in liquid paraffin and without any vitamin were tested on eleven patients. Though insufficient in number for a final conclusion, these tests strongly suggest the probability that both the vitamin fraction and the iodized fatty acid fraction are necessary for definite effect, and that neither is effective alone. The authors conclude that the preparation vitiodum is as effective in Graves's disease as Lugol's solution, while the limits of its beneficial action closely resemble. No gastro-intestinal disturbances were produced by the preparation, either during or following its administration. They advocate further research, not only to investigate the relation between the vitamins and thyroid and iodine metabolism but to check accurately a much larger number of cases during the administration of vitiodum.

495 Open Operation for Congenital Dislocation of Hip

W. R. MACAUSLAND (*Surg., Gynecol. and Obstet.*, November, 1928, p. 697) advocates a more extensive use of open operative procedure in the treatment of congenital dislocation of the hip as presenting certain advantages over manipulative methods. An open operation is indicated in children from 4 to 8 years of age in whom one or two closed manipulations have been unsuccessful. It becomes the method of choice

in older children and adolescents in whom manipulative treatment is liable to cause extensive trauma, in adults open operation is necessary to correct deformity and produce satisfactory functional results, and to relieve pain and stiffness with avoidance of late developing arthritic complications. Treatment aims at simple replacement of the femoral head in the acetabulum, with such reconstruction methods as may produce satisfactory functional and anatomical results. After a two day preparation of the operation field the capsule and joint cavity are explored through an incision curving downwards from the anterior superior spine to the outer part of the thigh, and any obstacle to reduction is removed. This is obtained by a combination of abduction and internal rotation movements, with the help of the author's "congenital hip skid" to lever the head into the cavity. A plaster spica from the breast iliac to the ankle is worn for eight weeks, with the hip in abduction and inward rotation and the knee flexed, after this period a new one is applied with the hip in 15 to 20 degrees abduction, and in marked inward rotation with the knee extended. At the end of six to ten weeks this can be removed and massage and passive movements commenced. Occasionally marked internal rotation may require osteotomy later, but this should not be performed until motion in the hip is well established. At the operation such pathological changes may be found as an hour glass shaped constriction of the capsule anteroversion of the femoral neck, or an acetabulum filled with adherent tissue covered over with the inferior capsule in the presence of such alterations the closed method of reduction is useless.

496 Tonsillectomy in Arthritis and Rheumatic Diseases

J. SCHNEYER (*Nach Arch f inn Med*, October 15th, 1928, p 119) describes 208 cases of acute and chronic rheumatic arthritis, rheumatoid arthritis, myalgia, neuralgia, osteoarthritis deformans, Bechterew's disease (2 cases), and gonit (2 cases), in all of which tonsillectomies were performed. Of these patients, 152 were women and 56 were men, their ages ranged from 19 to 65 years. Schneyer does not recommend tonsillectomy as a routine procedure in all these diseases, and insists that care should be exercised in the selection of suitable cases. His conclusions are as follows: (1) In acute rheumatic polyarthritis, after the subsidence of acute symptoms, and in secondary chronic polyarthritis, tonsillectomy should always be advised regardless of the condition of the tonsils. (2) In "rheumatoid" diseases such as chronic infective rheumatoid arthritis, in neuralgia, and in myalgia, tonsillectomy should be performed only when the tonsils are unhealthy, and the connexion of the tonsillitis with the arthritis or other rheumatic disease appears to be probable. Caution should be exercised in cases of primary chronic polyarthritis, since this disease is but rarely associated with tonsillitis. (3) In osteoarthritis deformans, Bechterew's disease, and gonit the author has never seen any improvement following tonsillectomy.

497 Phrenicectomy in Pulmonary Tuberculosis

G. ICHOK (*Arch de med, cir y exp*, October 20th, p 446) maintains that excision of the phrenic nerve is chiefly indicated in ulcerative, inactive, and localized pulmonary lesions which show a spontaneous tendency to retract, in such cases it may produce a cure. This result is not affected by the localization of the lesions or the presence of adhesions. It depends almost entirely on the retractility of the diseased tissue. As a subsidiary operation phrenicectomy may be of assistance in association with an incomplete artificial pneumothorax, or in facilitating suspension of artificial pneumothorax and maintaining its beneficial effects. It may also improve the results of high or low thoracotomy, act as an adjuvant in any extensive thoracoplasty, and facilitate the surgical treatment of tuberculous empyema. In conclusion Ichok declares that the sequelae of phrenicectomy should be considered much more from the qualitative than from the quantitative aspect, since this operation frequently has unexpected results.

498 Naevus-carcinoma.

A. BLAIR AITKEN (*West African Med Journ*, October 1928, p 118) reports the case of a male European aged 48, who appeared at first to be suffering from acute lymphangitis spreading to the left axillary glands from the region of a small pigmented naevus the size of a sixpenny piece on the flexor aspect of the forearm. He had been under treatment for prickly heat with secondary sepsis in the form of numerous small boils and pimples all over the body and had several other smaller naevi. The lymphatic inflammation subsided after a week, but a large hard mass of glands remained in the axilla. A small fragment excised from the axillary mass was found to be *carcinomatous* in the mean time the naevus remained soft, and according to the patient's

statement, was only very slightly enlarged since two years previously, when he had noticed it to be somewhat tender to touch. A palliative operation was performed, the naevus being excised with a wide margin and the axilla cleared. The patient died with widespread secondary deposits six months after first reporting at hospital. The author remarks that this case is of interest in view of the rarity of malignant changes in pigmented naevi and the rapidity of fatal spread of growth from a focus showing little or no changes clinically. He comments on the apparent lymphangitis, and raises the question whether this was really a manifestation of the spread of cancer cells, also whether the sepsis resulting from prickly heat could have had any influence in determining malignant changes in the naevus.

Therapeutics

499 Treatment of Infections of the Urinary Tract.

K. KELSTED and L. SCHUBERT (*Acta Med Scand*, September 28th, 1928, p 268) insist that for an accurate estimate of the value of any therapeutic method in treating infections of the urinary tract the nature and locality of the infection must be known. Urine obtained by ureteral catheterization under strict asepsis must be examined chemically, microscopically, and bacteriologically, since otherwise the exact site of the disease cannot be determined. The most common infecting microorganism is *B. coli*, then come *B. proteus*, *Staphylococcus aureus* and *albus*. Treatment includes the use of autogenous or stock vaccines, irrigation with various antiseptic solutions, such as silver nitrate (1 to 2 per cent), boric acid, or mercurochrome, and flushing the urinary system from kidney tubules to urethra with large quantities of fluid combined with various antiseptics. The authors recommend keeping the urine acid and administering hexamethylene tetramine or salol. Calcium chloride and ammonium chloride increase the acidity of the urine. In some cases alternating acidification and alkalinization of the urine are advantageous. The authors treated 70 patients in all, comprising 28 cases of pyelitis and 42 of cystitis, pyuria was associated with bacilluria in all. Most of the cases were complicated by such conditions as sonitic mobility, carcinoma of the bladder, and prostatic hypertrophy, with heart disease. In all of the 70 cases the authors combined the administration of calcium chloride and ammonium chloride with urinary antiseptics, such as hexamethylenetetramine, salol, or hexyl resorcinol. Only six cases of pyelitis and six cases of cystitis became free from bacteria under internal treatment. The remaining 36 cases of cystitis, after prolonged internal treatment, required further local treatment—1 per cent silver nitrate solution for three consecutive days. Disinfectants are said to be useless for preventing phosphatic encrustation of catheters and Pezzor tubes. The authors believe that antiseptic treatment is comparatively useless when large quantities of fluid are administered, reduction of the urine to half its volume increases greatly its bactericidal power. They conclude that it seems advisable to combine treatment with restriction of the fluid intake.

500 Liver Treatment of Pernicious Anaemia.

T. ORDWAY and L. W. GORHAM (*Journ Amer Med Assoc*, September 29th 1928, p 925) report excellent results from the administration of liver or a potent extract in twenty five of their own cases of pernicious anaemia and in 553 cases collected from the literature. Of these, 387 were treated with liver and 191 with extract alone. In the first 12 of the 25 cases now reported the Minot-Murphy diet was rigidly adopted, in the remainder a liberal diet with sufficient liver was found to be equally effective. The authors believe that strict adherence to the original Minot-Murphy diet is not essential and that the administration of hydrochloric acid is unnecessary, since equally prompt improvement was obtained when this was omitted. The symptom changes were rapid and led to clinical recovery, though achlorhydria and advanced cord changes persisted almost without exception. The blood changes, all indicating stimulation and increased activity of the bone marrow, confirmed the findings of Minot, Murphy, and other workers. No failures occurred in this series, and lack of success in liver treatment is attributed to one of the following causes: infection or other complication, the giving of insufficient liver, incorrect diagnosis, the effect of multiple transfusions, and in exceptionally rare cases, possibly to a lack of reactive power of the bone marrow. Liver appears to exert a specific influence on the development of fanly erythrocytes but has no effect on the underlying pathological process, and hence cannot be termed a cure. The quantity given daily should be 1/4 to 1/2 lb, and monthly blood counts are necessary to gauge correctly the maintenance dose necessary for the patient. Attention is drawn

to certain risks. With the widespread use of liver in all types of anaemias, secondary anaemias due to operable surgical conditions, and which may yield to proper surgical treatment, are apt to be overlooked. Impotent extracts are a source of danger. While multiple transfusions are contraindicated, transfusion is of value in desperate cases to tide over the patient. Two cases of gout and a few of hypoglycaemia have been reported during treatment. These complications, as well as the possibility of remote renal effects after years of diet, should be borne in mind. E. H. HILARI (ibid., p. 928) reports similar benefits from liver administration in 24 cases (19 treated with liver and 5 with extract). The only departure from the Minot-Murphy diet was an increase in the low fat constituent so as to make the diet more palatable. Among 16 patients reaching the diet the average hospital stay was 37 days, and the average erythrocyte count and haemoglobin on discharge were 3.6 millions and 76 per cent, in 5 receiving the extract the figures were forty six days, 4 millions, and 83 per cent respectively. Two unusual cases are reported in detail.

501 Administration of Ergosterol in Rickets

P. ARMAND DELILE and J. BERTRAND (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, October 25th, 1928, p. 1418) regard the employment of irradiated foodstuffs as a valuable addition to the therapeutics of rickets. They have not made an extensive trial of irradiated milk because they found it difficult to administer to children on account of its very disagreeable taste, they therefore employed irradiated ergosterine. They report the case of a boy, aged 2, who was admitted with very definite signs of rickets, he had been badly fed and his weight was only 21 lb 6 oz. He could not stand. The frontal bone was bowed and the anterior fontanelle admitted two finger tips; the costal cartilages were overted with a rickety rosary, and the abdomen was prominent and flaccid. There was no evidence of tuberculosis, but the long bones showed typical rachitic deformities. The ossifying centres of the os magnum and unciform were alone visible in the skiagraph of the carpus. Two days after admission 20 drops of ergosterol daily was prescribed, without any other treatment, except heliotherapy when the sun was visible. Two months later the child was discharged, his weight was then 24 lb, his appetite was good, and he could stand and walk a few steps. Skiagraphs showed that ossification was proceeding rapidly. The authors have another child under the same treatment who is also making rapid progress. They claim that the results obtained greatly exceed those following natural or artificial heliotherapy, but they advise continuing the administration of ergosterol with light treatment to improve the muscular tone. They add that ergosterol is easily administered and promotes rapid calcification of bone, it will probably be of value in the treatment of decalcification of bone due to other causes.

Dermatology.

502. A Bacteriological Treatment of Ringworm

THE knowledge that many saprophytic fungi overgrow or inhibit the growth, *in vitro*, of many of the ringworm species led S. O. CHAMBERS and F. D. WEIDMAN (*Arch. Derm. and Syph.*, October, 1928, p. 568) to a further examination of the problem which included the bacteria. Ringworm of the toes was particularly studied; these skins being considered normal which appeared normal grossly and scrapings from which were negative for fungi. Fifty platings were made from the skins of four normal subjects, and the resulting colonies were purified, if necessary, by subculture. These were tested against *Tricophyton interdigitale* and other ringworm fungi, and fifty strains later identified as *B. subtilis* were found to have an inhibitory effect on the growth of these organisms. As the next step, 50 apparently normal toes and the toes of 50 patients showing more or less disturbance between the toes were examined for *B. subtilis*. It was found to be present in 35 of the normal cases and absent in 34 of the abnormal ones. Further tests with mixed cultures of *B. subtilis* and *T. interdigitale* showed that the bacteria inhibited the fungi in thirty four out of forty tests, and restrained them in the remainder. Finally, clinical tests were made on 20 patients suffering from dermatomycosis of the feet. Blood agar cultures of *B. subtilis* were used, the growth being removed and applied directly to the affected skin with no other treatment. After the first week 25 per cent improvement was noted, and 50 per cent after the second. The authors maintain that, while these tests do not completely substantiate the hypothesis that *B. subtilis* exists as a biological protector on apparently normal skins and is absent on fungus infected ones, they do not refute it. They also believe that

the improvement they obtain by this method warrants further investigation and encourages its application to other dermatoses in which the causative micro organism is known and is cultivable.

503 Eczema-Asthma Prurigo Complex

R. C. LOW and J. A. DRAKE (*Brit. Journ. Derm. and Syph.*, October, 1928, pp. 389 and 407) independently discuss the eczema asthma prurigo complex. That eczema and asthma frequently occur in the same patient, either simultaneously or alternately, has been recognized for some time, and sufferers from one may recover completely and some months or years later develop the other. Statistics compiled by other investigators also show that many cases of chronic eczema give a history of asthma, and vice versa. In order to overcome the confusion arising from looseness of terminology Low uses the term 'prurigo' to indicate "Hebra's prurigo," and the term "asthma eczema" for the condition described variously as "Bernier's prurigo," "spritzexudatives eczematoid," "chronic eczema," "pruriginous eczema," "flexural eczema," etc. A considerable proportion of chronic eczemas and asthmas give positive skin reactions to various proteins, suggesting that the same protein is responsible for both conditions. The fact that eosinophilia occurs in the blood in eczema, asthma, and prurigo, locally in the lungs in asthma, and in the skin in prurigo and eczema points further to the relationship of these conditions. Low concludes that asthma eczema and asthma are shown to be analogous in every respect from their clinical course, symptoms, hereditary tendencies, skin tests, and blood and tissue changes. Drake considers that the underlying basic factor in the asthma eczema prurigo complex is an inherent or acquired dysfunction or disharmony of the autonomic nervous system.

504 Pemphigus.

J. SABRAZES and J. TORLAIS (*Gaz. Heb. des Sci. Méd. de Bordeaux*, October 7th, 1928, p. 643) sum up the results of a prolonged study of this disease. They remark that true pemphigus must be distinguished from simple symptomatic pemphigoid rash, as there is a congenital bullous epidermolysis which is due to a special sensibility of the skin to external injuries, and there is also an acquired type. This vulnerability of the skin probably plays a large part in the development of certain cases of the disease, whether acute or chronic, and determines the outbreak of pemphigus in various toxæmia, septicæmia, anaphylactic, or endocrine states. Dühring's herpeticiform dermatitis belongs to the group of pemphigus, and the authors adduce evidence that congenital syphilis may be a cause, the histological changes which they describe and illustrate bear this out. They find that infective conditions of the kidney and liver may also be a cause of pemphigus. Eosinophilia was variable in its appearance, but was more commonly seen in the young. Other suggested causes are peculiarities in the vascularization and innervation of the skin and the retention of waste products.

Obstetrics and Gynaecology.

505 Anaesthesia in Gynaecological and Obstetrical Operations

According to T. HEYNEMAN (*Zentralbl. f. Gynäk.*, September 15th, 1928, p. 2427) the safest, most convenient, and most generally applicable mode of anaesthesia in gynaecological and obstetrical operations is open administration of ether. Chloroform is to be rejected on account of its harmful action on the heart and liver, since the introduction of ethyl chloride as a preliminary to ether narcotization, chloroform is not required except in exceptional cases in which profound muscular relaxation is necessary for the performance of difficult obstetric versions. Lumbar anaesthesia, in the author's and others' experience, is not free from danger, is unpleasant from the patient's point of view, and may be followed by headaches and paralyses. For these reasons it finds its application only in prolonged abdominal operations such as Wertheim's hysterectomy, and in patients with pulmonary contraindications to inhalation anaesthesia. Heyne has abandoned paravertebral anaesthesia as inconvenient and unrollable both from the patient's and surgeon's point of view, and sees little to recommend sacral anaesthesia. Intravenous administration of ether in septic cases is followed by temporary improvement in pulse and general condition. Local anaesthesia is not acceptable as a rule to patients, but its scope (in certain cases) in vaginal operations of all sorts, in Caesarean section, and in short abdominal operations. In the author's practice local anaesthesia has been replaced very largely by nitrous oxide, combined—especially in vaginal

operations—with other Gas anaesthesia is free from danger and unpleasant after effects, and is used in all vaginal operations, including radical hysterectomy for cancer of the cervix, on an average 50 grams of ether are required in addition. It is also employed for episiotomy, perineal suture, forceps applications, and vaginal Caesarean operations. In curetting operations bimanual exploration of the pelvis necessitates supplementary administration of ether, and for version, manual loosening of the placenta, and suture of cervical tears ether is preferable as inducing less bleeding and greater muscular relaxation.

506. Treatment of Inflammatory Adnexal Diseases.

C BUCURA (*Nieuw Arch. Ned. Geneesk.*, November 1st, 1928, p. 1530) advises expectant conservative treatment in adnexal inflammations, except when an abscess requires evacuation, or when there is no probability of recovery without an operation, since the prognosis, in regard both to freedom from pain and the possibility of subsequent conception, is more favorable when conservative treatment is combined with vaccine therapy. Sterility may result from a minor as well as from an extensive surgical intervention if the operation is performed while there is active inflammation; the degree of such activity is indicated by the temperature, leucocyte counts, blood precipitation tests, and the response to the hypodermic injection of a moderately large dose of gonococcal or mixed vaccine. If a positive reaction follows, operation should be deferred unless required by some emergency. In that case, although the patient's life may be saved, it is probable that the removal of all trace of disease may necessitate the sacrifice of all the internal genital organs. If, however, it is possible to defer operation until the symptoms of inflammation have subsided, vaccine therapy accelerates resolution of the inflammatory process. Bucura states that the great majority of recurrent adnexal tumours are due to gonorrhoeal or mixed infections. He advises the employment at first of a gonococcal vaccine followed, if necessary, by a polyvalent vaccine containing gonococci, streptococci, staphylococci, and *B. coli*, until all signs of inflammation have disappeared, this may entail treatment for two, three, or occasionally more months, after which an operation is permissible if necessary. In many cases sexual activity may thus be preserved and the danger of post-operative complications avoided.

507

Pylitis in Pregnancy

ACCORDING to J. HOFBAUER (*Arch. f. Gynäk.*, June 26th, 1928, p. 205) the use of antisepsis, whether given by the mouth or intravenously, in treatment of pylitis in pregnancy is contra-indicated by the fact that morbid conditions of the renal parenchyma are concomitant with almost every case. The diet should be regulated in order to exclude all but small amounts of protein, vegetables should be excluded in it, and copious hot draughts be administered containing substantial amounts of grape or milk sugar. Injections of pituitary extract should be given three times daily, besides its antipilegistic action, it induces vigorous contractions in the musculature of the ureter and promotes drainage of infected and obstructed urine. The injections are not, it is said, fraught with any danger of inducing abortion. Since dilatation of the ureter by no means always disappears after labour, the administration of pituitary extracts should be continued for at least a fortnight after delivery. Hofbauer believes that the excess of bile salts present in the blood during pregnancy is a contributory cause to the atony of the ureter, and on experimental grounds advises also the use of adrenaline in the therapeutics of pregnancy pylitis.

Pathology.

508

A Female Hormone.

IN response to Graves's demand for a standardized ovarian hormone E. LAQUEUR and S. E. DE JONGH (*Journ. Amer. Med. Assoc.*, October 20th 1928, p. 1169) recommend the standardized limpid watery solution to which they have given the name of "menformon," the preparation of which is based on American discoveries. Menformon produces oestrus in castrated rats and mice, and in all mammals tested increases the size of the juvenile uterus, vagina, and tubes. It induces growth of the mamma in both young females and males, small doses affecting the glandular secretory parts, larger doses the external parts also. Menformon increases metabolism only in castrated females, and not in castrated males, it has an antimasculine influence. It is non-toxic even when injected for many months at a time. It is soluble in volatile solvents and water, the purer it is the more soluble it is in water and the less in volatile agents. These are all true solutions being dialysable. Menformon is adsorbable, the less so the purer it is, is not volatile, and is very resistant to

heat, acids, alkalis, ferments, and reducing agents, but is susceptible to oxidizing agents. Probably it consists only of carbon, oxygen, and hydrogen. Menformon is considered to be a true hormone because it occurs in, and may be prepared from, normal organs, it produces certain effects that also occur in the normal individual, and it is present in body fluids apart from the places where it is formed. It occurs regularly in the blood and urine of both males and females. On subcutaneous injection it is resorbed at once without leaving any troublesome residue, in contrast to colloidal or oily solutions. In view of its perfect harmlessness, even in large intravenous doses, the authors advocate menformon for clinical use. In an editorial article on ovarian hormones and ovarian organotherapy (*ibid.*, p. 1194) reference is made to menformon, and it is pointed out that the fact that it can be obtained not only from the ovaries and urine of females, but also from the testes and urine of normal males, raises the question of specificity, and also the question whether the recent laboratory reactions are really reliable criteria of ovarian hormone reaction. While the various ovarian preparations are now sufficiently purified to be tried in cases of definitely uncomplicated ovarian deficiency, in most of the other disturbances of the female sex life other than ovarian factors are primarily involved. Negative results are therefore of little value in guiding further investigations in this important field.

509

Virus III Encephalitis

T. M. RIVERS and F. W. STEWART (*Journ. Exper. Med.*, November, 1928, p. 603) report some fresh work on Virus III. This virus is an active filterable agent indigenous to rabbits. Experimentally it has been shown to produce a high fever and characteristic lesions in the cornea, testicles, and skin, within the epithelial and endothelial cells of these lesions acidophilic nuclear inclusions are found, similar to those seen in varicella and herpes. Frozen and desiccated, and kept in sealed tubes on ice, it retains its virulence indefinitely even after fifteen months under these conditions the virus was still active. Its activity is also maintained for at least six weeks if infected testicular emulsions are mixed with equal amounts of glycerol and stored on ice. In the present work the authors started with a virus that had been stored for a long time, but all their subsequent experiments were performed with fresh material. They find that if 0.2 c.c. of infected testicular suspension is inoculated intracerebrally into rabbits encephalitis is frequently produced, as evidenced by the tremor, ataxia, irritability, circling, salivation, retention of urine, generalized tonic and clonic contractions of the skeletal muscles, or paralysis that follow. The results, however, were very irregular—occasionally all the rabbits inoculated died; at other times none of them died. Whether this was dependent on variations in the virulence of the infecting organism or on variations in the resistance of the rabbits was not determined. Histologically the picture was that of a meningo-encephalitis, not unlike that of herpetic encephalitis. There was a chronic meningitis, characterized by lymphocytic plasma cell, and endothelial cell infiltration, the perivascular sheaths of penetrating vessels were often distended with similar cells, nerve cells in the hippocampal region and in the cerebellum underwent hyaline degeneration, leaving a spongy reticulated zone of ground substance, and intranuclear inclusion bodies were found in nerve cells, glia cells, ependymal cells, endothelial cells, arachnoidal fibroblasts, and in cells of the choroid plexus. Though the encephalitis produced by Virus III is similar to that produced by the herpetic virus, experimentally showed that the two viruses were immunologically distinct.

510 Effect of Anthrax Bacilli on Tissue Cultures.

E. A. H. FRIEDHEIM (*O. R. Soc. de Biologie*, November 15th, 1928, p. 1467) previously found that fibroblasts from the hen, which is refractory to anthrax, appeared to be unaffected by the growth of anthrax bacilli in tissue cultures. In the present communication he has repeated his work with tissue cultures coming from the mouse—an animal susceptible to anthrax. Fibroblasts from the embryonic skin were cultivated in embryonic juice and plasma, anthrax bacilli, virulent or avirulent, were introduced into the same preparations. The results were similar to those with the hen. Even when the colonies of the bacilli were in extremely close apposition to the tissue cells the growth of these cells did not appear to be in any way interfered with, and it was not till the bacilli brought about an actual liquefaction of the medium that the growth of the cells was stopped. No difference was noticed whether the plasma in the culture came from a susceptible or a refractory animal. The author concludes that the mesenchymatous cells of susceptible animals are indifferent to anthrax bacilli, and that therefore natural susceptibility and immunity must be related to some other type of cell.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

511 Rheumatic Infection in Childhood

DISCUSSING the predisposing factors in infantile rheumatic infection, A. D. FORDYCE (*Med Journ and Record*, November 7th, 1928, p. 460) states that the hypothesis generally held is that the infecting agent of rheumatism under normal conditions and in natural sites is a harmless saprophyte, and that infection is the ultimate result of disturbed physical or chemical conditions which cause the development of a favourable environment, consequently, a necessary preliminary to infection—which is endogenous—is a derangement of metabolic activity or of organic constitution. Given such a suitable diathesis or constitution the selective spot for the rheumatic attack is the lymphoid tissue in the nasopharynx and intestine, and, as a result of infection, the danger sites in the viscera are the heart and brain (carditis and chorea). Fordyce advances as three chief predisposing factors of rheumatic infection in children: instability of the nervous system, digestive disorder, and weakness of the lymphoid defence. When all these are marked there is serious danger of heart infection and chorea. When nervous instability and digestive disorder alone are marked chorea is threatened. When lymphoid weakness is the sole prominent condition the danger is of heart infection, and there is little likelihood of chorea. The predisposing factors are simple and common, and for this very reason are difficult to control. Fordyce believes that given the opportunity of post natal supervision and treatment of predisposing factors, it would be possible to eliminate to a very great extent the scourge of rheumatic heart disease.

512. Premature Alopecia

J. SPITZ (*Liol and Cut Rev*, November, 1928, p. 733) states that the commonest cause of premature alopecia is seborrhoea or its allied condition, dermatitis seborrhoeica. In many cases this is doubtless complicated by hereditary predisposition. Local disease of the scalp such as ring worm, favus, impetigo, eczema, oryctolasis and lupus, or general conditions such as psoriasis, influenza, typhoid fever, syphilis, or pregnancy, may also be responsible. The prognosis depends upon the cause. The principal requirement in therapeutics is to treat the scalp so that it will receive a better blood supply. If debilitated the patient must first have his strength built up by ordinary tonics or general measures. On the theory that the alopecia may be due to endocrine disturbances, various extracts of the ductless glands, especially the thyroid and parathyroid, may be used. The scalp must be washed frequently, preferably with tincture of green soap, and energetically massaged at the same time. The patient should be advised to expose his hair to the sun as much as possible. In the belief that the alopecia is due to a parasitic infection, parasiticides such as ammoniated mercury and borie acid ointments are employed usually in combination with stimulants such as oil of cade, crude coal tar, chrysarolin, pyrogallol acid, resorcinol and sulphur, or salicylic acid. The ointments should not remain more than twelve or fifteen hours on the scalp, and should then be washed off with soap and warm water. The application should be made every other day rather than daily, for fear of over stimulation. Ultra violet rays are useful if there has been sufficient loss of hair to favour the access of the rays to the scalp. Spitz regards diathermy of great value, as it acts as a stimulant. The brush and comb should be thoroughly washed and dried at least once a week. The patient should be made to realize that the treatment is a prolonged one, and that it is only the dormant but still living follicles that can be stimulated to growth.

513 Effect of Strain on the Heart.

P. D. WHITE (*New England Journ Med*, October 25th, 1928, p. 801), in his consideration of the effects of strain upon the heart, calls attention to the factor of ventricular balance. The brunt of increased work falls initially upon either the right or left side of the heart, if failure of one side occurs it is not long before the other side fails, unless compensation is meanwhile established. Thus all degrees of failure of either ventricle or both, may be encountered. The author divides strain into intrinsic and extrinsic varieties. Intrinsic factors causing strain are essentially valvular defects and disorders of rhythm. While it is true that the condition of the myocardium is of vital importance, there has been a tendency to under estimate the embarrassments offered by severe mitral

stenosis or aortic incompetence. With regard to those conditions, it is believed that a less serious strain is imposed by combined regurgitation and stenosis of the mitral valve than by either separately, while in the case of aortic regurgitation the occurrence of some stenosis is a favourable event. Greater strain results from aortic incompetence when it is syphilitic in origin than when rheumatism is the etiological factor. In congenital heart disease the author believes that the degree of cyanosis is an index of the burden thrown upon the heart. Other intrinsic factors are pericarditis (acute and chronic), coronary disease, myocardial disease of infective or toxic origin, and disease of the great vessels. Of the arrhythmias, flutter and fibrillation represent greater strain than paroxysmal tachycardia unless this is of ventricular origin. Extrinsic factors are of less importance, with the exception of hypotension and hypertrophy. The chronic burden of high blood pressure may alone be sufficient to produce cardiac failure. Exercise, pregnancy, obesity and overeating, anaemia, nutritional diseases, and anaesthetics are some of the other extrinsic factors considered.

514 Pellagra and Alcoholism.

S. L. SWEITZER (*Minnesota Med*, November, 1928, p. 719) records his experience of an epidemic of eight cases of pellagra in Minnesota, seven in hospital and one in private, in which alcohol was a striking etiological factor, probably through its action as a disturber of nutrition. Though all need not be present in each case, there are said to be four cardinal symptoms of the disease, those consist of skin manifestations with the development of large bullae on the backs of the hands and fingers, and, in a few cases, the face and neck, involvement of the mouth mucous membrane, the tongue being coloured blood red or with red edges, severe intestinal diarrhoea and mental symptoms. The typical eruption on the back of the hands, red tongue, and diarrhoea established the diagnosis in the author's cases. All the patients had been drinking heavily, and the seven admitted to hospital had obtained denatured alcohol. Switzer considers that the alcohol by acting as a disturber of metabolism, caused the condition, although some other etiological factor must have been present also, seeing that the disease did not occur previously when alcohol was largely consumed.

Surgery.

515 Elephantiasis

A. P. BERTWISTLE and A. L. GREGG (*Brit Journ Surg*, October, 1928, p. 267) discuss elephantiasis as a disease of great antiquity which is common in parts in which *Filaria bancrofti* is prevalent, being less frequent in other tropical and subtropical places. It is less common in Germany and Austria than in the British Isles and France. It is a condition of hypertrophy and hyperplasia developing in a part as a result of excessive protein from lymphatic exudate. This is present as the result of infection, most frequently streptococcal, occurring in a part primarily presenting veins and lymphatic stasis. It may occur on any part of the body, but the most common sites are the legs (57 per cent) and the scrotum (38 per cent). The commencement of true elephantiasis dates from the first attack of lymphangitis occurring after an acute illness, such as tonsillitis or pneumonia and is manifested either as a phlebitis or erysipeloid attack with localized lymphatic inflammation, associated with pyrexia, abortion of vomiting, and general body pains. The disease progresses in three stages, the first being the smooth uniform swelling or thickening of the part, during which little discomfort is felt. In the second stage the skin shows definite thickening and coursing, and has an uneven ridged appearance, the muscles being hypertrophied to compensate for the increased burden. In the third stage the skin and subcutaneous tissues are greatly hypertrophied, and, in the case of a limb, are thrown into large folds separated by deep sulci, while in the scrotum there is diffuse rigidity. There is a liability to weeping fissures, indolent ulcers, and abscess formation. The intervals between the attacks of lymphangitis may either become greater or else the attacks may increase in number and severity until the lymphangitis causes deep abscess formation and septicaemia and the death of the patient. The first treatment of elephantiasis must be the discovery of the source of focal infection, which may be the teeth or tonsils, though pelvic appendicular or urinary infections may be responsible. The general health of the

patient must be improved by rest and better nutrition, vaccine therapy and sebum have also been used with marked success. Elevation of the affected part is essential, and deep and vigorous massage will help to restore the vitality of the affected tissues. If these methods of treatment are insufficient an operation must be considered, amputation being the only procedure for scrotal and breast enlargements. In the amputation of the scrotum special measures for ensuring lymph drainage are advisable, a new scrotum being formed, if necessary, by plastic methods. In the case of elephantiasis of the lower limbs, an exterior incision is made from the external malleolus to the mid Poupart line, a large slice of oedematous skin and subcutaneous fat is removed, and the aponeurosis removed three fingerbreadths through out the length of the incision. The skin is then sutured in contact with the muscles without drainage. The operation is conducted in stages. Kondoleon's operation holds out good prospects of a prolonged temporary, if not a permanent, cure.

516 Acute Appendicitis

C. EGGERS (*Amer. Journ. Surg.*, October, 1928, p. 335) emphasizes the importance of early diagnosis and treatment as the means of lowering the rather high mortality of acute appendicitis. This mortality he considers to be due to delay on the part of the patient, to the administration of a laxative which increases peristalsis and delays the walling off of an inflamed appendix, and also to incorrect diagnosis. The symptoms are abdominal pain, cramp-like in character, in the epigastrium or round the umbilicus, vomiting, which may be severe or intermittent, and fever, which invariably develops as the inflammatory process evolves. The pulse rate is generally elevated, and may be one of the most valuable indications for diagnosis. A blood count nearly always shows leucocytosis, with an increase in polymorphonuclear neutrophils. An operation should be performed as soon as possible after acute appendicitis has been confirmed, the incision being made over the region of rigidity and tenderness, and ensuring adequate exposure. Out of 250 patients admitted to hospital, 112 had perforated at the time of operation, but the mortality was only 9, or 3.6 per cent. Death was due in 7 cases to peritonitis, and in the other 2 cases to septic thrombophlebitis with multiple liver abscesses.

517 Angioma and Trauma

O. ANDREI (*Arch. Ital. di Chir.*, September, 1928, p. 105), who records three illustrative cases, states that Angelioli has recently revived the view of Lücke and Pilzer that a traumatic haematoma may be transformed into an intra-muscular cavernous angioma. According to Angelioli, the blood after escaping from the vessels does not coagulate, but remains fluid as in haemophilia, and more or less infiltrates the muscular tissue without forming a circumscribed haematoma. The connective tissue elements of the tissue infiltrated by the blood then assume a protective endothelial function, and a cavity is formed in which the blood remains fluid and communicates with the circulation. Kelaczek, on the other hand, out of 95 cases of angioma on record, could find only 8 cases in which there was a history of trauma, and Andrei himself has been unable to trace a single instance of angioma which could be attributed to trauma among 63,000 cases of trauma of all kinds and degrees. He is therefore very sceptical as to the possibility of any causal relation between trauma and angioma, especially if the trauma had been a single one, and attributes more importance to congenital malformation of the vessel or vascular area to which the violence has been applied.

518 Varicose Ulcer

H. O. MCPHEETERS (*Surg., Gynecol. and Obstet.*, October, 1928, p. 459) discusses the etiology, pathogenesis, and treatment of varicose ulcer of the leg. Since the causation is due to a trophonutritive disturbance resulting from the stagnation of serum in the tissues secondary to varicose veins, it is held to be obvious that the correct procedure is to cure the veins first and the ulcer second, the converse being wrong both in theory and practice. The actual ulceration commences with gangrene and separation of the superficial layers of the skin, and there does not appear to be any relation between the type of bacterial infection and the rate of healing, neither can any constant organism be regarded as a specific cause. Cure is most rapidly effected by the injection of sclerosing solutions to obliterate all the affected veins together with the application of pressure by means of a rubber sponge and elastic support, and the judicious use of skin grafts in the case of large ulcers. McPheeters advocates the use of a tourniquet in order to retain the solution locally and so ensure its sclerosing effect, he uses a 20 per cent salt solution for extensive cases, the

60 and 76 per cent calomel for any isolated varix which may be left, or in cases of one long vein with a distinctly positive Trendelenburg sign, and the 30 and 40 per cent sodium salicylate solution in those occasional cases which do not respond to salt or calomel. In order to avoid any recurrence after healing continued support for some time is essential in all cases, and especially in those in which skin grafts have been used.

Therapeutics.

519

Treatment of Gonorrhoea

BELIEVING that the many failures in the treatment of gonorrhoea are due to the lacunar and follicular lesions caused by the gonococcus in areas into which medicaments can with difficulty penetrate, M. DURAY (*Brussels Med.*, October 14th, 1928, p. 1650) describes the method of Maisler, in which a gas is employed which, by dilating the canal, smooths out the mucosa and facilitates the access of injections into all the urethral folds and diverticula. Maisler advocates the use of an oxydizing agent such as neol, with a specific antiseptic, silver proteluate. The method is simple and rapid. A catheter with an olive shaped bulb is first passed to determine the seat of the lesions. Then 2 c.c.m. of neol, pure or diluted according to the patient's sensibility, is allowed to flow down the catheter. The neol passes back freely along the length of the canal and thus impregnates it. The patient then fixes the catheter by pressing the urethral canal towards the gland, and 1 c.c.m. of 10 per cent silver proteluate is injected. Some rapid to and fro movements of the piston are then made until the froth produced overcomes the patient's pressure on the canal. This treatment is painless, non-irritant, and well endured, the majority of patients tolerating even pure neol, and no accidents from its use have been noted. It has proved efficacious in acute infections, but Duray has obtained cures in cases of chronic urethritis that were refractory to ordinary measures, and in some cases of chronic prostatitis in which the treatment was applied to the posterior urethra combined with massage of the gland. The method is said to be of especial benefit in cases of long standing prothrititis.

520 Protein Therapy in Peripheral Vascular Diseases

As peripheral gangrene is limited almost entirely to males in the prime of life, A. W. ALLEN and R. H. SMITHWICK (*Journ. Amer. Med. Assoc.*, October 20th, 1928, p. 1161) emphasize the importance of therapeutic measures that permit restoration of function. The mechanism of the disease is an obliteration of the main arteries which, developing slowly, permits the establishment of the collateral circulation, if the compensatory process is inadequate gangrene occurs. The authors believe that the vasomotor system plays a more important part than pure mechanics in the production of the disease. Following the suggestion of Brown, a small series of 25 cases (a tabulated report of which is given) were treated with intravenous injections of typhoid vaccine. The vaccine consisted of a mixture of typhoid bacilli with paratyphoid A and B, 1 c.c.m. containing 2,500 million organisms. For the average patient the initial dose was 0.05 c.c.m., but if the reaction following this dose was too severe, a smaller dose was given in subsequent injections. The desired reaction is an elevation of the mean temperature of 3° to 5°F. At the commencement weekly injections were given, the time interval being increased as the patient improved. The treatment was combined with proper hygiene and minor surgical procedures when necessary. The results obtained were encouraging, and of 19 patients with complete disability 12 were able to return to work. Non-specific foreign protein (typhoid vaccine) gives a marked reaction, much like that following periaxillary sympathectomy, with a definite relief from pain and a beneficial change in the lesions. The authors believe that this method hastens the development of an adequate collateral circulation more effectively than any conservative measures hitherto suggested.

521

Stramonium in Parkinsonian Rigidity

E. A. CARMICHAEL and T. H. K. GREEN (*Quart. Journ. Med.*, October, 1928, p. 51) record the results of a clinical and histological study of the effect of stramonium and hyoscine upon the Parkinsonian syndrome. In order to compare their effects upon tone, fine movements, and rapidity of movement, they recorded graphically in five patients by means of a special apparatus the time taken to stretch a voluntarily relaxed group of muscles, an ergograph tracing of a series of repeated fine movements, and a simple voluntary movement. The results were checked by normal controls. The administration of hyoscine subcutaneously and by mouth, and of stramonium

by mouth, was found to reduce considerably the length of the rigidity curves, which became smooth in contour, and these effects coincided with a marked clinical improvement in the rigidity of the arm muscles. The ergograph tracings changed remarkably in the direction of the normal, and the bradykinesia tracings correspondingly improved. The authors conclude that these investigations prove that the administration of tincture of stramonium in large doses 45 to 60 minims being given three times a day, lessens the Parkinsonian rigidity and increases the ability to perform fine rapid movements. The tremor is not affected, but the mental condition is improved. They found it to be at least as efficient as hyoscine subcutaneously in large doses, and better than hyoscyne given by the mouth. The drug may be continued over a long period of time rarely producing toxic effects which may occur more in elderly patients suffering from idiopathic paralysis agitans than in younger post-encephalitic. This action, however, is palliative and not curative, and the whole tincture of stramonium is more efficacious than atropine or hyoscyamine.

522. Vaccine Treatment of Rheumatism

R. LAUTIER (*Bull. Soc. de l'her.*, October 10th, 1928, p. 183) during the last four years has treated 152 patients with a vaccine prepared from two strains of *Acholema bacillus* (*Clostridium aerogenes capsulatus*) from his report 32 cases are excluded in which the treatment had not been continued sufficiently long to be conclusive. Of the remaining 130 patients 117 made a complete recovery or showed considerable improvement, in 10 there was slight improvement, and in 3 the treatment completely failed. The 117 successes consisted of 12 cases of acute or subacute articular rheumatism, 37 cases of nodal cardiac rheumatism or rheumatic myocarditis, 46 cases of chronic myocardial rheumatism and 22 cases of various rheumatic manifestations such as angina pectoris, sciatica, and thyroiditis. Lautier is convinced that many lives would be saved if a wider use was made of the vaccine, and adds that it should always be employed in cases which are refractory to sodium salicylate.

Anaesthetics.

523. Blood Changes during Surgical Anaesthesia.

R. L. MACKAY and S. C. DYKE (*Brit. Journ. Anaesth.*, October, 1928, p. 61) discuss certain changes in the blood observed in a series of 39 patients under general anaesthesia, 13 of whom received in addition local and regional anaesthesia. The investigation was undertaken mainly to ascertain whether any relationship existed between the variation of the sugar content and the regrouping of the buffering substances. Samples of blood were taken from an arm vein before induction and at half-hour intervals afterwards, chloroform being used only for induction, the anaesthesia being maintained by C.E. mixture or ether. While no conclusions can be drawn in respect of chloroform administration, the results showed that there was no significant difference in this respect between the two last anaesthetic procedures. The only selection made was of cases probably requiring anaesthesia of longer duration than one hour. The chloride content of the plasma rises during anaesthesia, while that of the whole blood remains constant, there being a 'shift' of Cl ions from the red cells to the plasma. The fixed CO₂ of the plasma diminishes rapidly at first but the fall tends to become slower and to cease altogether as the anaesthesia proceeds. Meanwhile the blood sugar rises quickly at first becoming slower later, and gradually reaching the original level. No apparent relationship exists between the extent and duration of the variation of the chlorides and the fixed CO₂ of the plasma on the one hand, and of the sugar content of the blood on the other, there appeared to be no significant differences in the behaviour of the phenomena observed as between cases operated upon under local and regional anaesthesia and general anaesthesia alone.

524. The Heart during Anaesthesia.

H. M. MARVIN (*New England Journ. Med.*, September 20th, 1928, p. 547), in his discussion of the heart during anaesthesia, calls in question the widespread belief that anaesthetics and operations entail stress and strain on the heart. The various circulatory disturbances that are apt to occur do not generally indicate cardiac insufficiency—for example, the onset of irregularity is but the manifestation of an abnormal rhythm long recognized and treated, while lowering of the blood pressure often indicates impending shock, which again does not depend upon incompetency of the heart. In support of his contention that the burden of anaesthesia is but slight, the author has made frequent blood pressure and pulse rate observations during the course of operations lasting several hours, and has found little or no alteration in these readings

when elevation of pressure and increased pulse rate occur, they are no more than those incidental to the activities of daily life, with the exception, therefore, of a phyllophobic incompetence, in which sudden death is specially apt to occur, any heart functioning adequately in everyday life will tolerate anaesthetics well. If the history or physical signs point to congestive failure, rest and digitalis are urgently indicated prior to operation. When an immediate operation is imperative and advanced failure is present a fairly large dose of a digitalis preparation should be given intramuscularly during the operation, administration being continued orally on recovery from the anaesthetic. The author condemns the pre-operative use of digitalis as liable to promote post-operative lowering of the blood pressure. The only arrhythmias that should occasion anxiety are dropped beats not the result of digitalization or representing a form of sinus arrhythmia, and high grades of heart block. The use of chloroform in these cases is regarded as always contraindicated, in very young children ether is often the best anaesthetic. For patients with cardiac disease in general, ethylene is recommended as the ideal anaesthetic, while nitrous oxide should be the second choice.

525. Treatment of Ether Bronchitis.

D. HAYWARD (*Zentralbl. f. Chir.*, October 6th, 1928, p. 2501) refers to the good results recorded by several writers as following the intramuscular injection of ether in post-operative bronchitis, which was recommended by Bior, one writer employs ether with oil of turpentine. Hayward's experience extends over two years and has been very favourable. It has convinced him that the intramuscular injection of ether in post-operative bronchitis and bronchopneumonia is superior to the usual treatment by expectorants. In thirty-two cases one injection sufficed, two patients required a second injection, and in one case the intramuscular injection was given three times.

Obstetrics and Gynaecology.

526. The Uterine Musculature in Pregnancy

H. KLIPPER (*Bruxelles Med.*, November 4th, 1928, p. 1) reports a series of histological observations on the changes in the smooth muscle fibres of the uterus during pregnancy. Small pieces of uterine tissue, several millimetres thick, were obtained at Caesarean operations, and, for comparison from hysterectomies of the gravid uterus at three to four and a half months. The preparations were fixed with Bensley's liquid and stained by Benda's method with alizarin crystal violet. The simple hypertrophy of all the uterine tissues, which begins in the early weeks and continues to about four months, was confirmed, but from this time new phenomena were observed. First, the chromaticity of the sarcoplasm and nucleus increased, then, at the periphery of the cell, there appeared a fine clear zone. This zone increased in size, probably by a process of hydration. Innumerable fine centripetal fibrils gradually appeared in this transparent zone, uniting the peripheral envelope (which consisted of bigger fibrils arranged longitudinally) with the chromophilic sarcoplasm, which appeared to be the substance from which the contractile fibrillar material was derived. At the moment of maximum hypertrophy the sarcoplasm was clear, but traversed longitudinally, transversely, and obliquely by very many fibrils clearly stained by alizarin and crystal violet. They were in a state of relaxation, or in large or small nodulations according to the degree of contraction. At or just before term degenerative changes began to appear such as alterations in the nuclei, decoloration of the fibrils, hydropsy of the cell, and finally total histolysis. At the same time fibroblasts made their appearance in the intercellular tissues. These were very chromophilic and took the form of muscle cells but remained opaque until they reached the size of the ordinary hypertrophied cells, when they cleared towards the periphery and apparently assumed the function of the old cells. At term, therefore it appeared that the uterine muscle bundles contained original fibres in process of maturation, others in full maturity in process of histolysis, and, in addition, a large number of fibroblasts in all stages of evolution.

527. Radium Treatment of Myoma Uteri

J. IKEDA (*Zentralbl. f. Gynak.*, September 29th, 1928, p. 2514) has treated 723 cases of myomata in the last twelve years in 79 cases an intravaginal hysterectomy was performed, and in 76 radium alone was used. The majority of patients were between 35 and 50 years of age, and 30.4 per cent were sterile. The tumours varied greatly in size, most of those reaching to above the umbilicus were removed by operation. The chief symptom was irregular bleeding then came

menorrhagia, and in a few dysmenorrhoea, also pressure symptoms according to the size of the tumour, and anaemia. In doubtful cases a preliminary diagnostic curettage was performed. The radium was usually placed in the cavity of the uterus, the dose was repeated three to five times at the end of the second, third, and fifth weeks, and the radium was left in for twenty-four hours or less when given more often. The total dose in milligram hours ranged from 1,593 to 20,885, the size of the tumour had less to do with the dose required than its consistency and vascularity, a small dose sufficing for a soft tumour. There were some complaints of nausea and vomiting, and in a few cases of raised temperature and actual pain the radium had to be removed, one case ended fatally owing to the patient's disobedience to instructions. Of the 76 cases treated, in 91.3 per cent metrorrhagia was arrested, in 83.3 per cent menorrhagia ceased, and in 9.2 per cent menstrual disturbances were less pronounced, in most instances menstruation ceased after two or three returns, and the uterus and tumour diminished in size until no trace of the tumour was to be found. Both subserous and submucous tumours were treated equally satisfactorily. Of 79 operation cases one patient died of septic peritonitis. The results are thus similar from both methods, but the author considers operation to be not without danger, whereas radiation can be safely performed by general practitioners if they have mastered the technique, it is the treatment of election in many cases, particularly where operation is feared.

528 Tuberculosis of Bartholin's Gland.

While inflammation and suppuration of Bartholin's gland is usually ascribed to gonococcal infection, W. D. FULLERTON (*Journ. Amer. Med. Assoc.*, October 20th, 1928, p. 1175) states that this may be due to other organisms (streptococci, staphylococci, *B. coli*), and that, unless gonococci are recovered from the genitalia, injustice may be done to the patient. Tuberculosis of Bartholin's gland is rarely recognized and is probably overlooked, since only three cases have been recorded. The author reports and describes another case, in which microscopic examination of the gland showed typical tubercle formation with slight secondary infection. The patient had an unusual vaginal discharge, and showed signs of tuberculous infection in the lungs and possibly also in the bowel. Fullerton adds that these four cases show that tuberculosis of Bartholin's gland does occur, either as a primary condition or secondary to tuberculosis elsewhere. The chronicity of the condition, the absence of the usual signs of acute inflammation, the thin watery clear or brownish discharge, and the absence of gonorrhoeal infection are the signs which suggest a tuberculous origin of an infection in this situation.

529 Suprapubic Cystotomy and Operation for Vesico-vaginal Fistula.

D. MÉRÉL (*La Gynéc.*, August, 1928, p. 467) in a case in which two operations for vesico-vaginal fistula had been unsuccessful, performed suprapubic cystotomy six days before a third and otherwise similar operation. The cystotomy tube was taken out on the fifteenth day and the fistula was found to be closed. Four other cases of low vesico-vaginal fistula have since been dealt with successfully on the same lines, but MéréL now prefers to open the bladder ten days before the operation and to drain the cystotomy wound for about twenty days. High fistulae, he remarks, are to be approached by the transvesical route, and cystotomy constitutes a necessary part of the operation. Recently Bloch has advocated non-closure of the suprapubic incision, and Marion and others, a transvesical repair of fistulae, have tied a tube in the bladder.

Pathology.

530 Ulcerative Processes of the Oesophagus.

J. FRIEDENWALD, M. FELDMAN, and W. F. ZINN (*Arch. Int. Med.*, October, 1928, p. 521) have made an experimental investigation of the diagnostic problems associated with oesophageal ulceration. In their experiments ulcers of variable depth were produced in sixteen dogs, and healing was subsequently traced by x-ray and oesophagoscopy examinations. After simple scarification the lesions produced gave no signs after a week, while even deep uncomplicated ulcers tended to heal rapidly. The administration of large quantities of hydrochloric acid to dogs in which ulceration was present produced chronic ulcers similar to those found in the stomach, while penetration and perforation were apt to follow. On the other hand, if no ulcer, or a healed ulcer, was initially present there were no pathological results of acid administration. By producing a steady flow of barium along the oesophagus into the stomach the x-ray signs of ulceration were observed. These were of three types: filling defects projecting from

the oesophageal outline, those partly displacing this outline, and spastic defects. The first type presents the most direct evidence of ulceration, and may sometimes be best observed by the retention of barium in the crater when the opaque meal has just passed out of the oesophagus. Deep penetrating ulcers are often more easily demonstrated when the oesophagus is well filled. The second type of defect often accompanies an ulcer crater, and may be seen in its immediate neighbourhood or on the opposite wall. Spasticity is found most commonly below the level of the lesion, it is of the tapering type, and may be so pronounced as to cut off completely the barium meal. Oesophagoscopy examination showed the ulcers to be well defined, with smooth bases bleeding easily when touched, even in long-standing ulcers definite induration and thickening were not noted. With fully established ulceration dysphagia was observed, but diet influenced very little the healing process. The lesions produced in the experiments were found on microscopic examination to present appearances similar to those of gastric or duodenal ulceration in man.

531 Liver Fractions in Pernicious Anaemia.

In their endeavours to ascertain whether certain constituents of liver are as effective as whole liver in pernicious anaemia R. WEST and EMILY G. NICHOLS (*Journ. Amer. Med. Assoc.*, September 22nd, 1928, p. 867) have already shown that the filtrate derived from a 60 per cent alcoholic extract of liver, treated with ammonium sulphate, was effective in raising the blood count. Further work on the commercial extract prepared by Cohn's method is now reported. This extract was dissolved in water and cleared with lead acetate, the lead being removed from the filtrate by hydrogen sulphide or sulphuric acid. A saturated solution of calcium phosphotungstic acid in 3 per cent sulphuric acid was added until no further precipitation occurred. The precipitate was dissolved and suspended in 75 per cent acetone and broken up with barium. The decomposed phosphotungstates raised both the red cell and reticulocyte counts, and were next fractionated by Kössel's silver method, silver acetate being used. The two silver precipitates were combined, decomposed with hydrogen sulphide and administered to a patient for ten days, but without effect. The silver filtrate, after removal of the silver was reprecipitated with phosphotungstic acid and decomposed as stated, and this material gave effective results. Precipitation of the active material with mercuric acetate has produced very feeble clinical responses. Three pure substances have also been tried as substitutes: choline with a negative result, and glutathione and ornithine with probably negative ones. The best fractions prepared had the following properties: nitrogen, from 12 to 14 per cent, amino-nitrogen, 20 per cent of nitrogen, which increases after acid hydrolysis to about 40 per cent, phosphorus, none, sulphur faintest traces, iron, none found. The analysis for copper is not finished, but probably none is present. Organic tests gave the following reactions: Biuret +, Diazo +, Hopkins-Cole weak +, naphthol test for arginine +. Polar scope readings indicated a weak dextro rotation.

532. A Serological Study of *Bacterium pseudotuberculosis rodentium*.

H. SCHÜTZE (*Arch. f. Hyg.*, 1928, 109, p. 181) has made a receptor analysis of eighteen strains of *B. pseudotuberculosis rodentium* cultivated from various animals. Morphologically and culturally, with one or two minor exceptions, these strains were identical, biochemically likewise they gave the same reactions, the main sugars fermented being glucose, maltose, mannite, and salicin. Serological analysis was performed by means of the agglutination and absorption of agglutination reactions. Two antigens were demonstrated, a flagellar and a somatic. The flagellar or H antigen appears only in cultures incubated at a low temperature—about 25°C. This is thought to be of considerable interest because it is known that it is only in cultures grown at this temperature that motility of the organisms is observed. The somatic or O antigen is formed at all temperatures of growth. The H antigen is destroyed by heating at 100°C for half an hour, and is therefore heat-labile, the O antigen is not destroyed at this temperature, and is therefore heat-stable. The H antigen was found to be common to all the strains, with the exception of one, which contained only O antigen. On the other hand, there was a marked difference in the type of O antigen possessed by the different strains. It was possible to differentiate these strains, postulating three groups on the basis of this antigen content. Group 1 contained twelve strains, Group 2 contained five, and Group 3 contained one strain. Moreover, both Groups 1 and 2 could be further subdivided into two subgroups. The remarkable observation was made that the antigen of Group 2 was closely related to the O antigen possessed by the Derby, Reading, *B. paratyphosus* B, and *B. agrippae*, equinus types of the *Salmonella* group.
